Computed Tomography of the Pelvis

John A. Spencer, Sarah E. Swift

The principal clinical applications of computed tomography (CT) of the pelvis are in staging of pelvic cancers, assessment of major bony and soft tissue injury, and investigation of suspected postoperative and other post-treatment complications. Access to spiral CT technology is now widespread, and its strengths and weaknesses are well understood. The recent introduction of multislice technology promises reduced examination times with further refinements in contrast enhancement, volumetric, and multiplanar techniques. These developments suggest a bright future for pelvic CT, but there are few studies comparing multislice CT with conventional or spiral CT and with other competing modalities in key pelvic applications, such as cancer staging.

During the 1990s, pelvic CT has been challenged by developments in ultrasonographic and magnetic resonance imaging (MRI). The introduction of specialized endoluminal probes and endoluminal and pelvic surface coils, respectively, for ultrasound and MRI has improved the staging of small and confined pelvic cancers. Further, there are increasing concerns about the risk to patients with potentially curable cancers from ionizing radiation. For these reasons, ultrasonography and MRI have replaced CT in the initial assessment and follow-up of a number of pelvic cancers.

This chapter discusses current indications for pelvic CT in the initial staging and further management of pelvic cancers, in the assessment of major pelvic trauma, and in the characterization and management of pelvic masses and fluid collections. The appearances of pelvic lesions commonly encountered as incidental findings in body CT are also described.

Normal Anatomy

The pelvis is an osseous ring that consists of the innominate bones laterally and anteriorly, the sacrum and coccyx posteriorly. The sacrum lies between the two innominate bones, its alae supporting the psoas muscles, and the lumbosacral nerve trunks (Fig. 44-1). Each innominate bone is composed of three fused parts: the ilium, ischium, and pubis. Within the innominate bone is the acetabulum, which is contained within the inverted Y formed by the anterior (iliopubic) and posterior (ilioischial) columns. The triangular-shaped anterior and posterior columns are con-

nected by the quadrilateral plate, which forms the medial acetabular wall (Fig. 44-2).

The pelvis is divided into the *true pelvis* and the *false pelvis*. The iliac wings bound the false pelvis and the iliac fossae, containing the ascending, descending, and sigmoid colon; small-bowel loops; the psoas and iliacus muscles; and the major neurovascular pedicles (see Fig. 44-1). The paired rectus abdominis muscles form the anterior border of the false pelvis. The true pelvis lies below the sacral promontory, contains the pelvic organs, and is separated inferiorly from the perineum by the urogenital diaphragm.

The pelvic muscles are normally symmetrical and are well visualized on CT. Psoas major passes caudally along the anterolateral border of the pelvis, tapering gradually to pass beneath the inguinal ligament anterior to the hip joint, and inserts onto the lesser trochanter of the femur (Figs. 44-3 and 44-4; see also Fig. 44-1). The iliacus is a fan-shaped muscle that fills the iliac fossa and narrows rapidly to insert on the lateral side of the psoas tendon and lesser trochanter (see Fig. 44-3). The femoral nerve lies in the fat plane between the psoas and iliacus muscles and passes caudally to lie under the inguinal ligament lateral to the femoral artery (see Fig. 44-3). The gluteus minimus, glu-

Figure 44-1. Normal anatomy. CT scan through contrast-filled ascending and descending colon in the iliac fossae shows the paired rectus abdominis (R), psoas (P), and iliacus (I) muscles. The common iliac arteries (curved arrows), common iliac veins (v), and lumbosacral trunks (straight arrows) are located anterior to the ala of the sacrum. The inferior epigastric arteries (arrowheads) are related to the posterior rectus muscles.

Figure 44-2. Normal anatomy. CT scan through the femoral heads shows anterior column (A), quadrilateral plate (arrow), and posterior column (P) of the acetabulum.

teus medius, and gluteus maximus muscles lie posterior to the innominate bones (see Fig. 44-3).¹⁷¹

The muscles within the pelvis are divided into two groups:

1. The true pelvis muscles: the levator ani and the coccygeus.
2. The muscles that originate within the pelvis and form part of the pelvic wall: the obturator internus and the piriformis.

The levator ani and coccygeus muscles compose the urogenital diaphragm, which is the floor of the pelvic cavity (see Fig. 44-4). This structure is pierced by the urethra, vagina, and anus. The piriformis and obturator internus muscles form most of the lateral sidewall of the true pelvis (Fig. 44-5). The obturator internus muscle also extends into the perineum to form the lateral boundary of the ischiorectal fossa (see Fig. 44-4). The greater sciatic foramen lies between the ischial spine and sacrum, and the

Figure 44-3. Normal anatomy. CT scan at the inferior sacroiliac joints shows the external iliac arteries and veins medial to the iliopsoas muscles (IP), which enclose the femoral nerves (arrowheads) and posterior dividing branches of the internal iliac arteries and veins (arrows). The gluteus minimus (MIN), gluteus medius (MED), and gluteus maximus (MAX) muscles compose the buttocks.

Figure 44-4. Normal anatomy. CT scan through the symphysis pubis shows the obturator internus muscle (OI) and obturator externus muscle (OE) on either side of the obturator foramen and the psoas muscle (PS) inserting on the lesser trochanter of the femur. Other muscles are the pectineus (P), sartorius (S), rectus femoris (R), tensor fasciae latae (T), and gluteus maximus (G) muscles. The pelvic diaphragm (arrows) separates the anus (A) from the ischiorectal fossae (I).

sciatic nerve passes through it on the anterolateral aspect of the piriformis muscle (see Fig. 44-5).^{50, 126}

The perineum is a diamond-shaped space below the urogenital diaphragm bounded anteriorly by pubic symphysis, laterally by the inferior pubic rami and ischial tuberosities, and posteriorly by the coccyx.¹⁵⁸ The triangular ischio-rectal fossae are bordered laterally by obturator internus, medially by the pelvic diaphragm, and posteriorly by the gluteus maximus muscles (see Fig. 44-4).

The abdominal aorta divides to the left of the fourth lumbar vertebra into the common iliac arteries (see Fig. 44-1), which course laterally and caudally dividing opposite the L5-S1 disc space into the external and internal iliac arteries. Caudal to the aortic bifurcation, the inferior vena cava is formed by the confluence of the common iliac veins at the level of the fifth lumbar vertebra. The external iliac arteries pass along the anteromedial border of the iliopsoas muscles. The internal iliac arteries lie posteriorly

Figure 44-5. Normal anatomy. CT scan through the sciatic notch shows the sciatic nerves (straight arrows) anterior to the piriformis muscles (P) and the obturator internus muscles (arrowheads) along the pelvic sidewalls. The pelvic ureters (curved arrows) are immediately posterolateral to the pelvic peritoneal reflections.

Figure 44-6. Pelvic lymph nodes. CT scan through the bifurcation of the external iliac artery and vein anteriorly (*straight arrow*) and the internal iliac vessels posteriorly (*arrowhead*) shows a classic right hypogastric lymph node metastasis (*curved arrow*) from cancer of the prostate gland.

on the lumbosacral plexus, course toward the greater sciatic foramen, and divide into multiple branches at the level of the inferior sacroiliac joints (see Fig. 44-3). Only the superior and inferior gluteal arteries are consistently seen on CT as they exit the sciatic notch. The external and internal iliac veins lie medial and posterior to the corresponding arteries.

Pelvic lymph nodes are classified according to accompanying vessels. The *common iliac lymph nodes* are located lateral and posterior to the arteries. The *hypogastric node* is situated at the bifurcation of the external and internal iliac vessels (Fig. 44-6). The *external iliac lymph nodes* are arranged in three chains:

1. The *lateral chain* on the lateral aspect of the external iliac artery.
2. The *middle chain* anterior and medial to the external iliac vein.
3. The *medial chain* posterior to the external iliac vein against the pelvic sidewall.

The obturator node is considered one of the medial external iliac nodes.¹⁶⁸ The most common internal iliac nodes identified on CT are located anterior to the piriformis muscle, around the inferior gluteal artery and vein (Fig. 44-7). The superficial inguinal lymph nodes lie distal to the inguinal ligament in the subcutaneous fat anterior and medial to the femoral artery and vein. A posterior iliac crest node has been reported to lie in the iliac fossa between the psoas and iliacus muscles.²⁶

The pelvic ureters cross anterior to the common iliac artery bifurcation and course posterior to the peritoneal reflection (see Fig. 44-5). At the sciatic foramen, the ureters course medially toward the lateral angle of the bladder. In the male, they terminate anterior to the seminal vesicles (Fig. 44-8). In the female, the ureters lie lateral or posterior to the ovaries and then course 1 to 2 cm from the lateral border of the cervix, where they pass through the cardinal ligaments to enter the bladder (Fig. 44-9).

The urinary bladder is a midline structure. It indents the parietal peritoneum, which reflects over the dome, to form

Figure 44-7. Pelvic lymph nodes. CT scan through the sciatic notch shows bilateral obturator lymph node metastases (*arrows*) from recurrent prostate cancer posterior to the external iliac veins (*v*) and a larger left internal iliac node metastasis (*N*) confluent with the piriformis muscle and posterior to the left internal iliac pedicle (*arrowheads*).

Figure 44-8. Normal anatomy. CT scan shows the seminal vesicles (*arrows*) between the bladder and rectum and the left pelvic ureter entering the bladder (*arrowhead*).

Figure 44-9. Normal anatomy. CT scan with delayed images through the cervix (*C*) shows triangular cardinal ligaments (*arrowheads*) tapering laterally and contrast-filled pelvic ureters (*arrows*) anteriorly.

Figure 44-10. Normal anatomy. CT scan shows normal prostate gland (P) between bladder and rectum and pelvic diaphragm formed by the levator ani muscles (arrows).

the intraperitoneal paravesical fossae laterally. It is of variable shape and size, depending on the amount of urine present. Urine is of near-water attenuation on unenhanced images.⁴

The male internal genital organs are the prostate gland and the seminal vesicles. The seminal vesicles are two extraperitoneal lobulated pouches located superior to the prostate between the bladder and the rectum (see Fig. 44-8). They vary in size both in different patients and in the same individual on serial examinations. The prostate gland lies posterior to the symphysis pubis and anterior to the rectum, between the base of the bladder and the pelvic diaphragm (Fig. 44-10). It is of soft tissue attenuation, but the zonal anatomy cannot be reliably distinguished even after intravenous (IV) contrast enhancement.

The female genital organs are the ovaries, fallopian tubes, uterus, and vagina. The position of the ovaries is highly variable, but they are usually located posterolaterally at the level of the uterine fundus and round ligaments (Fig. 44-11). They lie in a shallow depression, the ovarian fossa, which is bounded by the external iliac vessels laterally and the ureter posteriorly.

Figure 44-11. Normal anatomy. CT scan through the uterus (U) and ovaries (O) shows round ligaments (arrows) tapering anterolaterally over the external iliac vessels.

In premenopausal women, normal ovaries are usually identified and their appearance may vary from soft tissue to more cystic attenuation, reflecting the presence of physiologic cysts or follicles. In postmenopausal women, the ovaries are often not identified.

The uterus appears as a soft tissue mass lying between the bladder and rectum. The myometrium shows intense contrast enhancement. A low-attenuation central area may be demonstrated reflecting fluid within the endometrial cavity. The uterus is divided into the *body (corpus)* (see Fig. 44-11), which has a triangular appearance on axial CT, and the *cervix* (see Fig. 44-9) which appears more ovoid. The cervix may also show contrast enhancement.

The broad ligaments are two fibrous sheets extending laterally from the uterus to the pelvic sidewall and covered on their anterior and posterior surfaces by peritoneum. They are not routinely seen on CT unless they are outlined by ascites. Between the leaves of the broad ligaments is the parametrium, which contains uterine and ovarian vessels (Fig. 44-12), fallopian tube, and round ligament. The round ligaments demarcate the superolateral border of the uterus and ascend anterolaterally over the external iliac vessels, pass through the inguinal canal, and insert in the labia majora (see Fig. 44-11). The triangular cardinal ligaments are located at the base of the broad ligament and fan out from their attachments at the cervix to insert on fascia covering the urogenital diaphragm (see Fig. 44-9).¹⁶⁵ The uterosacral ligaments arise in continuity with the cardinal ligaments and pass posterolaterally around the rectum to insert on the sacrum.

The proximal two thirds of the rectum is covered by peritoneum on its anterior and lateral sides, forming the pararectal fossae laterally. The distal one third of the rectum is covered only by anterior peritoneum, which reflects onto the seminal vesicles and bladder in the male to form the rectovesical pouch. In the female, the peritoneum covering the bladder and rectum is divided by the uterus and vagina into a shallow, anterior vesicouterine recess and a large, deep, posterior rectouterine fossa (pouch of Douglas

Figure 44-12. Normal anatomy. CT scan through the uterus (U) shows a tortuous left uterine artery and prominent vascular plexus (white arrows) running within the broad ligament. In the left obturator fossa a contrast-enhanced structure (black arrow) probably represents a pelvic varix.

or cul-de-sac). The cul-de-sac is continuous with the pararectal and ovarian fossae.⁴

The extraperitoneal spaces of the pelvis are complex. Anterior to the peritoneum and posterior to the transversalis fascia, the umbilicovesical fascia spreads inferiorly from the umbilicus to surround the urachus, obliterated umbilical arteries, and urinary bladder.⁵ This fascia divides the anterior extraperitoneal fat into a perivesical space and a prevesical space. The bladder, umbilical arteries, and urachus lie within the confines of the umbilicovesical fascia in the small perivesical space. The large potential prevesical space lies anterior to the umbilicovesical fascia and includes the retropubic space or space of Retzius. The prevesical space has potential extensions into the anterior abdominal wall (rectus sheath), the parametria (round ligaments), the inguinal canal and scrotum, properitoneal fat, and the retroperitoneum.⁵

Examination Technique

Adequate opacification of small and large bowel by an oral contrast agent is essential for most CT examinations of the pelvis. Administration of 10 mL of a water-soluble iodine-based agent, such as diatrizoate meglumine (Gastrografin), diluted in 200 mL of water 6 to 12 hours before the study (or as an overnight preparation) ensures good colonic opacification. An additional 1 L of 3% solution given over 1 hour immediately before the CT study opacifies the small bowel. Some institutions use an additional 100 mL of dilute water-soluble contrast per rectum, especially when there is a previous history of pelvic malignancy. If bowel opacification remains suboptimal, delayed images following additional oral contrast agent or alteration of the patient into prone or decubitus positions may be useful. A vaginal tampon aids the identification of the vaginal canal and the level of the vault and may be helpful in women with gynecologic malignancy.

IV contrast enhancement is a major part of most CT examinations. It is used to delineate vessels, to help differentiate lymph nodes from vascular structures, to detect lesions, and to enhance solid components within tumors and other complex masses. We administer 100 to 150 mL, depending on patient size, of non-ionic 300 mg/mL of iodine concentration contrast material using a pump injector at a rate of 3 mL/second. Scanning the pelvis at approximately 35 to 40 seconds after the commencement of the injection allows enhancement of the bladder wall prior to filling of the bladder with excreted urinary contrast agent. This is important when bladder tumors are being imaged.

For many systems, the images obtained can be rapidly reviewed; when the distinction of lymph nodes from venous structures is uncertain, further study at 180 seconds shows venous enhancement. Use of delayed scans after 10 to 15 minutes allows injected contrast agent to opacify the ureters and the urinary bladder. This is particularly relevant when the scan is being performed in the context of trauma.

Scan parameters and technique can be varied according to the specific requirements of the individual study. When the pelvis is scanned alone in the context of an orthopedic examination, attention is paid to bony detail with narrow-slice collimation and overlapping reconstructions, which

allow subsequent multiplanar reconstructions (MPRs) if required. Although oral and IV contrast agents are avoided and the radiation dose can be kept low, the trade-off is loss of soft tissue detail. For vascular applications dedicated to the aortoiliac segments, attention must be paid to the administration of IV contrast agent. Faster injection rates of up to 5 mL/second deliver the contrast agent as a compact bolus and early timing of image acquisition (e.g., at 30 to 35 seconds after the start of the injection) ensures an arterial-phase study. The use of automated-exposure devices, such as Smart Prep (General Electric) or a CARE bolus (Siemens), facilitates accurate timing of vascular examinations. Oral contrast agents again should be avoided because they may degrade images using postprocessing MPRs, multi-image projections (MIPs), and surface-shading techniques.

The pelvis is usually scanned as part of an abdominopelvic study in the setting of oncology, trauma, or suspected sepsis. Such studies are subject to competing requirements for information in terms of volume examined, detail provided, and timing relative to the contrast bolus. For example, the radiologist needs to obtain local detail regarding pelvic tumors as well as wider coverage of the liver and retroperitoneum for metastatic assessment.

Single-slice spiral CT offers the option to scan in either the craniocaudal or the caudocranial direction. In the latter the study is timed to reach the liver at approximately 60 seconds from the start of IV contrast injection. Two separate breath-hold volume acquisitions using different prescriptions for collimation and pitch, such as 8- to 10-mm collimation for the abdomen and 5- to 7-mm collimation for the pelvis, optimize information and coverage. An alternative approach might be to cover the whole area in a single acquisition; however, the cost is then extended pitch—and therefore helical stretch—and, consequently, decreased image quality.

New multislice technology offers the potential for wider flexibility, although the full range of its clinical applications has yet to be evaluated.³² Because there is no dependence on spiral pitch and the reconstructed slice, width can be chosen retrospectively.⁴⁶ Faster acquisition times and finer collimation with multislice spiral CT reduce the trade-off between detail and coverage. The concurrent acquisition of multiple slices results in a reduction in scan time, allowing coverage of an entire anatomic region during optimal phase of enhancement while maintaining high spatial resolution. A twofold or threefold increase in volume acquisition rate with comparable image quality to a single-slice system has been shown to be obtainable.^{68, 69} Scanning at speeds higher than this is possible, but there is some loss of image quality. This problem, however, may be acceptable in certain circumstances, such as with traumatized or uncooperative patients. In practical terms, the main advantage of the speed gain with multislice systems is the ability to obtain the required volume of information at high spatial resolution within a single breath-hold.

Depending on imaging requirements and patient cooperation, the focus of the examination can be ultra-high speed, intermediate speed, or high z-axis resolution (isotropic) imaging.³² As an example, 2.5-mm collimation and a 3.2-mm effective slice thickness, with 50% overlapping reconstructions and a 1.6-mm reconstruction interval, result in

excellent quality MPRs for the pelvis. In the abdomen, 5-mm collimation, a 6.5-mm effective slice thickness, and 5-mm reconstruction interval offer an excellent compromise in speed, coverage, and spatial resolution.

Rapid reconstruction times are also important in view of the large amount of data and number of images generated. This capability to rapidly review an examination contributes to increased patient throughput. There are, however, concerns about the increasing radiation dose associated with diagnostic CT, and care should be taken to responsibly utilize the technique.¹⁰⁶

Lymph Nodes

CT is used for evaluation of lymph node metastasis from a wide variety of primary pelvic tumors and in the staging of lymphoma. The major diagnostic criterion for CT evaluation is nodal size. During the 1990s, the upper limit of size considered "normal" for pelvic nodes has fallen from a diameter of 15 mm to 10 mm or less. As metastatic nodes enlarge, most become more rounded; thus, the maximum short-axis dimension (MSAD) is used in CT assessment. When staging pelvic cancers with spiral CT in the early vascular phase at 40 seconds after injection of contrast the pelvic veins are not opacified and it may be difficult to distinguish these from lymph nodes. A second phase of scanning at 180 seconds opacifies the pelvic veins.^{48, 184}

The evidence supporting the use of smaller lymph node sizes comes principally from a unique study that correlated the size of normal pelvic lymph nodes on CT examinations before and after lymphangiography in men with stage I testicular cancer (i.e., with no likelihood of pelvic nodal metastasis). More than 98% of pelvic nodes had MSADs below 10 mm.¹⁶⁷ With the 99th percentile for MSAD used at individual pelvic sites, the upper limit of normal sizes varied between 7 and 10 mm (Table 44-1). For most pelvic cancer staging purposes, lymph nodes in the important obturator and internal iliac groups more than 8 mm in MSAD should be regarded as abnormal.¹⁶⁷ Support for these recommendations comes from a helical CT study of women with cervical cancer in which an MSAD of 8 mm was found to be optimal for evaluation of pelvic nodal metastases.¹⁸⁴

In that study, CT and MRI were equivalent for nodal assessment. The overall accuracy of CT in this assessment

using spiral CT was 89%.¹⁸⁴ Use of size thresholds as small as 5 mm has been described but with a reduced accuracy of 80%.⁴⁸ These data compare with older criteria for assessing lymphadenopathy for a combination of pelvic tumors, giving accuracies of 73% to 77%.^{89, 168} There will always be a significant false-negative fraction owing to micrometastases in normal size lymph nodes, variously estimated at 15% to 40%.^{89, 168} Conversely, there is a significant false-positive fraction because lymph node enlargement may result from benign causes such as chronic lymphadenitis, fatty replacement, and reactive hyperplasia.

Whatever size threshold is chosen to discriminate normal from metastatic lymph nodes, these two simple facts remain:

1. Lower thresholds are more sensitive to metastasis but result in more false-positive results and hence a lower specificity and positive predictive value.
2. Higher thresholds improve specificity but yield more false-negative results.

Use of a 5-mm threshold had a positive predictive value of only 43%; with a 10-mm threshold, however, the positive predictive value rises to 85%.^{48, 184} Imaging strategies employing low threshold size may be combined with fine-needle lymph node biopsy to improve positive predictive value and specificity (Fig. 44-13).¹²² High threshold sizes are appropriate when a therapy or intervention is withheld after a confident CT diagnosis of lymph node metastasis. In such circumstances, CT prevents unnecessary intervention in patients with unequivocally involved nodes, whereas patients with smaller nodes are sampled by staging lymphadenectomy.

A number of normal structures may be mistaken for pelvic lymph nodes, including unenhanced pelvic sidewall vessels, unopacified pelvic bowel loops, and the normal ovary (Fig. 44-14). Conversely, nodal metastases from some pelvic tumors may be confused with vascular structures. Enhancing lymph node metastases are seen with a number of pelvic cancers, notably bladder (Fig. 44-15).⁷¹ Other abnormal appearances in metastatic lymph nodes include necrosis and calcification. Necrosis in lymph node deposits from squamous carcinoma may have a similar

Table 44-1. Upper Limit of Normal Size for Pelvic Lymph Nodes

Lymph Node Group	Maximum Short-Axis Dimension (MSAD)*
Internal iliac	7 mm
Obturator	8 mm
Common iliac	9 mm
External iliac	10 mm

* Using the 99th percentile for maximum short-axis dimension at individual pelvic sites.

Adapted from Vinnicombe S, Norman A, Nicolson V, Husband JE: Normal pelvic lymph nodes: Evaluation with CT after bipedal lymphangiography. *Radiology* 194: 349-355, 1995.

Figure 44-13. Lymph node biopsy. CT scan during fine-needle aspiration of right hypogastric nodal (N) metastasis from recurrent bladder cancer.

Figure 44-14. Ovary-mimicking metastasis. CT scan through the uterus (U) shows an unusual lateral position for an ovarian cyst (C) simulating a hypodense obturator lymph node metastasis.

appearance to simple cystic structures such as the ovary (Fig. 44-16). Ring enhancement in smaller necrotic nodal metastases may mimic venous thrombosis. Calcifications may be seen in metastases from papillary serous adenocarcinoma from a variety of sites in the female genital tract (Fig. 44-17).

Assessment of nodal metastasis from pelvic cancers remains a great challenge for CT, an imaging technique still largely relying on crude size criteria. Other factors to consider in assessment are lymph node site in relation to the primary tumor, the local tumor (T) stage, and the clinical context. For most pelvic cancers, the incidence of nodal metastasis increases with T stage, and there are predictable sites and patterns of lymph node metastasis for individual tumors discussed further in the relevant sections. Accurate nodal assessment is most important when management options are solely determined by CT findings.

Figure 44-15. Lymph node metastasis. CT scan through the iliac vascular pedicles shows an enhancing left external iliac nodal metastasis (N) from newly diagnosed high-grade bladder cancer.

Figure 44-16. Metastatic cervical cancer. CT scan through the uterus (U) and right ovary (O) shows bilateral cystic/necrotic obturator lymph node metastases (N) from known cervical cancer.

Technical factors and size thresholds chosen and the use of CT-guided biopsy thus vary with clinical indications and should reflect local clinical practice.

Bladder Cancer

Bladder cancer accounts for 4.5% of all malignant tumors and 2% of cancer deaths in the United States. About 80% of cases occur in men with the peak incidence in the 6th and 7th decades. Cigarette smoking is the most important recognized causative factor. Ninety percent of bladder tumors are transitional cell carcinomas. Some tumors express squamous cell differentiation, a feature that may predominate with chronic bladder irritation due to calculi and in areas of endemic schistosomiasis. Most bladder tumors are found around the trigone and posterolateral

Figure 44-17. Calcified nodal metastases. CT scan through the uterus shows a distended endometrial cavity (E) and multiple nodal metastases (arrows) from a papillary serous adenocarcinoma of the endometrium.

walls of the bladder, and this proximity to the ureteric orifices results in hydronephrosis with some invasive tumors. About one third of patients have multifocal tumors.

Hematuria brings patients to medical attention early. The diagnosis of bladder cancer is usually made at cystoscopy, increasingly performed with a flexible endoscope. Most patients at diagnosis have early-stage superficial papillary disease. These patients require no further imaging and undergo cystoscopic follow-up. Formal transurethral resection is usually required to assess the depth of bladder wall (muscle) invasion. This is combined with bimanual examination under anesthesia (EUA) of the patient to evaluate perivesical extension. Examination under anesthesia is of limited value in determining perivesical tumor extension, and thus most patients with muscle invasive tumors undergo further imaging. In follow-up, superficial tumors may progress to muscle invasive tumors.

In the United States, clinical staging criteria are based on the Jewett-Strong-Marshall classification. Elsewhere in the world and particularly in Europe, the Tumor-Node-Metastasis (TNM) system predominates. The two schemes are compared in Table 44-2.

There are three principal options for management of bladder cancer:

1. Tumors without muscle invasion are managed by cystoscopic means (see earlier), with or without adjuvant intravesical therapies.
2. Muscle-invasive tumors, including those with minimal perivesical extension, may be managed by either cystectomy or radiation therapy.
3. Tumors with advanced perivesical extension or metastatic disease are usually managed with palliative chemotherapy or radiation therapy, although palliative cystectomy is used in selected cases for symptom control.

The key role of CT scanning is thus in staging of muscle-invasive tumors, as follows:

Table 44-2. Tumor-Node-Metastasis (TNM) Classification and Jewett-Strong Staging System of Urinary Bladder Cancer

Jewett-Strong Staging		TNM Histopathologic Findings
0	T0	No tumor
0	Tis	Carcinoma in situ
0	Ts	Papillary tumor, confined to epithelium (mucosa)
A	T1	Tumor invades subepithelial connective tissue (lamina propria)
B1	T2a	Tumor invades superficial muscle (inner half)
B2	T2b	Tumor invades deep muscle (outer half)
B2	T3a	Tumor with microscopic invasion of perivesical fat
C	T3b	Tumor with macroscopic invasion of perivesical fat
D1	T4a	Tumor invades surrounding organs
D1	T4b	Tumor invades pelvic or abdominal wall
D1	N1-3	Pelvic lymph node metastases
D2	M1	Distant metastases
D2	N4	Lymph node metastases above the bifurcation

Figure 44-18. Confined bladder cancer. CT scan through bladder tumor (T), outlined by urine, of stage T2 or earlier on the anterior wall. Incidental note is made of the median (arrowhead) and medial (arrow) umbilical ligaments.

Stage B/T3a (or earlier) tumors are “confined” to the bladder, show no outer wall abnormality, but may produce a smooth focal contour bulge (Fig. 44-18).

Stage C/T3b tumors produce an irregular outer bladder wall or soft tissue infiltration into perivesical fat in the region of the tumor (Fig. 44-19). Either a soft tissue mass or stranding may project beyond the outer contour of the bladder.

Stage D1/T4a,b tumors extend locally to invade surrounding organs or to the pelvic sidewall musculature, principally the obturator internus and the pelvic diaphragm or the anterior abdominal wall for tumors arising at the dome.

Although cystoscopy is the best means of evaluating intravesical tumors, CT may be valuable when resection has been incomplete or has been limited by complications,

Figure 44-19. Stage T3b bladder cancer. CT scan through the trigone of the bladder shows an extensive enhancing tumor invading the perivesical fat (arrowheads) and extending up the left ureter (arrow), which is dilated.

Figure 44-20. Bladder cancer in a diverticulum. CT scan through a thick-walled and trabeculated bladder with multiple diverticula. A, Early-phase image shows a calculus in the right-sided diverticulum (*arrow*) but possibly a tumor in the left-sided diverticulum (D). B, Delayed excretory-phase image shows tumor (T) both filling the diverticulum and intravesically at the same level.

such as bleeding, and when a tumor arises in a bladder diverticulum (Fig. 44-20). An intravesical tumor may manifest as a regular or irregular wall thickening, a sessile lesion, or a polypoid mural lesion. In extreme cases, an irregular tumor mass fills the bladder lumen (Fig. 44-21). Some tumors show a high-density cap. This usually reflects calcification but may be due to keratin from squamous carcinoma.⁹¹

Both the intraluminal and extraluminal components of the bladder cancer show IV contrast enhancement (see Fig. 44-18).⁷² With contrast-enhanced spiral CT, the enhancing bladder wall is contrasted against unopacified urine (see Figs. 44-18 and 44-19) to outline the intravesical extent of the tumor. However, pseudotumors may result from

swirling ureteric jets of contrast opacified urine.¹²⁰ Delayed images are occasionally required for clarification by outlining intravesical tumor against excreted urinary contrast material (see Figs. 44-20 and 44-21).

A number of other pitfalls exist. Caution is also required in interpretation of early postoperative CT examinations. There may be bladder wall thickening and perivesical fat “infiltration” from the mechanical or thermal trauma of resection, and perivesical extraperitoneal fluid collections may result from transmural extravasation of irrigation fluids. Chronic wall thickening may result after surgery or radiation therapy.¹³³ The bladder must be adequately distended, and when there is a urinary catheter in place, it should be clamped before the CT examination. However, overdistention of the bladder may result in underestimation of wall thickening and may obscure fat planes between the bladder and adjacent structures. Good opacification of pelvic small bowel loops is essential, and in cases of advanced local disease, additional rectal contrast administration may be valuable in delineating the rectosigmoid colon.

Spiral-CT data sets have been used to produce three-dimensional (3D) simulations of the bladder known as *virtual cystoscopy*.^{110, 166} This technique has not had a wide impact on clinical practice.

The overall accuracy of CT for staging bladder cancer in various studies using nonspiral CT was between 64% and 81%.^{74, 85, 141} For lymph node assessment, accuracy varied from 83% to 92%. The false-negative rate of 25% to 40% resulted from microscopic tumor deposits in normal-sized lymph nodes.^{85, 117} The false-negative rate can be reduced by use of smaller nodal size criteria and by fine-needle aspiration biopsy of lymph nodes.⁴² However, this approach is not widespread in the management of bladder cancer.

The other understaging CT error is failure to demonstrate microscopic invasion of the perivesical fat.^{74, 117} This may not necessarily compromise outcome after cystectomy if the surgical margins are unaffected. CT overstaging

Figure 44-21. Bladder sarcoma. CT scan in the delayed excretory phase through the bladder shows a partially necrotic tumor (T), a high-grade sarcoma, filling most of the lumen, with an extravesical tumor on the right (*arrow*).

errors result from either mistaking absence of fat planes between pelvic organs as evidence of local invasion or misinterpreting normal structures abutting the bladder as perivesical tumor extension. Up to 27% of stage B/T3a or earlier tumors were overstaged because of loss of fat planes between the seminal vesicles and posterior bladder wall.⁸⁵ Overdistention should be avoided, and decubitus or post-voiding images may help separate the bladder from the pelvic sidewall. Additional oral contrast administration with delayed or decubitus images may be necessary to distinguish tumor from unopacified pelvic small-bowel loops.

Data on the accuracy of spiral CT for bladder staging are limited, and there have been few older comparative studies of dynamic incremental CT and MRI. Although there were no statistically significant differences in overall staging accuracy, there was a trend toward superiority of MRI over CT. MRI is helpful in delineating tumors at the dome and bladder base and in assessing invasion of the prostate gland.^{2, 13, 72, 81}

CT is an excellent method for detecting recurrent bladder cancer after cystectomy.^{37, 93, 121} The abdomen should also be examined because isolated abdominal metastases occur in recurrence of this disease.³⁷ CT findings include a mass in the cystectomy site, pelvic and retroperitoneal lymphadenopathy, and liver metastases.^{37, 93, 121} Bony destruction may be seen with pelvic tumor recurrence (Fig. 44-22), and inspection of images on appropriate window settings may be necessary to detect lesser degrees of cortical erosion when tumor abuts bone.

Unusual bladder tumors include urachal carcinoma, small cell carcinoma, sarcoma, and metastasis. Eighty-five percent to 90% of urachal tumors are mucinous adenocarcinomas.¹³ These are represented by either a mass at the bladder dome with a superior midline extravesical component or a mass anterosuperior to the bladder dome along the expected midline course of the urachus. The mass has low attenuation (because of mucin production) with peripheral or central calcification.¹³ Small-cell carcinoma of the bladder tends to metastasize widely to the pelvic

and retroperitoneal lymph nodes, the liver, the lungs, and even the brain.¹¹ An unusual histology should be suspected when a bulky endophytic or exophytic tumor is showing mixed enhancement patterns (see Fig. 44-21), although high-grade transitional cell cancers can result in similar appearances.

Prostate Cancer

Prostate cancer is the most common cancer in men in the United States and the second most common cause of cancer mortality in men. Prostate cancer occurs in about 20% of men, and for several years its incidence has been increasing. Most prostate cancers are adenocarcinomas and are graded according to the system of Gleason: a score of 1 up to 5 is given for each of two predominant histologic patterns in the tumor, giving a range of scores from 2 (indolent) up to 10 (highly aggressive).

Formerly, the diagnosis was confirmed mainly by digitally guided prostate biopsy or from the chippings of transurethral resection of the prostate gland. Now the diagnosis is commonly made by transrectal ultrasound-guided biopsy prompted by either an abnormal digital rectal examination or an elevated prostate-specific antigen (PSA) level. There is accumulating evidence that a patient's PSA level and the Gleason score of the tumor can be used to determine the need for a bone scan and cross-sectional imaging assessment of lymph node metastasis as part of initial staging.^{124, 145} It is unlikely that CT will reveal evidence of lymph node metastasis in a man with a PSA level below 20 ng/mL and a Gleason score below 7.

In clinical practice, the TNM staging system is now more commonly used than the American Urological Association (AUA) staging system (Table 44-3). There is no consensus on treatment. Generally, patients with stage T2 or earlier, N0 (AUA stages A and B) prostate cancer, without extraprostatic extension or lymph node metastasis, are candidates for radical local therapy. This may involve radical prostatectomy or radiation therapy. Treatment selection is influenced by PSA level, tumor grade, patient age, and co-morbidity as well as patient and physician preference. For preoperative assessment MRI with pelvic surface or endorectal coils is now considered the most accurate staging technique, although early claims of accuracies exceeding 90% have not been realized in wider clinical practice.^{9, 139, 156}

CT is not effective in differentiating stage T2 or earlier from stage T3 tumors and thus is not used for this purpose as a preoperative staging test. CT has reported overall accuracies of 64% in detecting periprostatic fat invasion (stage T3a disease) and only 58% in detecting seminal vesicle invasion (stage T3b).¹²⁸ Stranding in the periprostatic fat may represent minor degrees of tumor extension, but similar appearances arise from inflammation, infection, or biopsy and from normal vascular structures within the rich periprostatic venous plexus. Invasion of the seminal vesicles may occur without density changes and asymmetrical enlargement may occur without invasion.

CT remains valuable in evaluating locally advanced disease: bulky T3b disease replacing the seminal vesicles (Fig. 44-23), involving the rectum (stage T4a) (Fig. 44-

Figure 44-22. Recurrent bladder cancer. CT scan shows right posterior pelvic tumor recurrence (T) eroding the ischial spine (arrow) and associated with a gas-fluid collection (F) from a fistula to the rectum (R). There is also metastatic nodal disease in the left obturator group (arrowhead) in this patient with recurrence after cystectomy.

Table 44-3. Tumor-Node-Metastasis (TNM) Staging Classification for Prostate Cancer

T	Primary tumor
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Clinically inapparent tumor not palpable or visible by imaging T1a Tumor incidental finding in 5% or less of tissue resected T1b Tumor incidental finding in more than 5% of tissue resected T1c Tumor identified by needle biopsy (e.g., because of elevated PSA) Tumor confined within prostate*
T2	T2a Tumor involves one lobe T2b Tumor involves both lobes Tumor extends through prostatic capsule
T3	T3a Extracapsular extension (unilateral or bilateral) T3b Tumor invades seminal vesicles
T4	Tumor is fixed or invades adjacent structures other than seminal vesicles: bladder neck, external sphincter, rectum, levator muscles, and/or pelvic wall
N	Regional lymph nodes NX Regional lymph nodes cannot be assessed N0 No regional lymph node metastasis N1 Regional lymph node metastasis
M	Distant metastases M0 No distant metastasis M1 Distant metastasis

* Tumor found in one or both lobes by needle biopsy, but not palpable or visible by imaging, is classified as stage T1c.
PSA, prostate-specific antigen.

**Figure 44-24.** Stage T4a prostate cancer. CT scan through the prostate (P) shows direct invasion of the rectum (R).

24), or extending to the pelvic sidewall (stage T4b). CT may be used to confirm the findings of digital rectal examination with advanced disease and to plan palliative radiation therapy. Bulky T3a disease may cause asymmetrical thickening, irregularity and nodularity of the prostate contour, and obliteration of fat planes with adjacent structures, including the loss of the angle between the prostate and the seminal vesicle. In some cases, the tumor enhances and is of higher attenuation than the adjacent prostate gland

**Figure 44-23.** Stage T3b prostate cancer. CT scan through the seminal vesicles shows enhancing prostate tumor (T) extending out of the base and replacing most of the left vesicle.

(see Fig. 44-23), a feature that is accentuated with rapid spiral acquisition in the early enhancement phase.

The overall accuracy for detection of lymph node metastases in prostate cancer is 67% to 93%.^{38, 95, 117, 172} This accuracy disguises a poor sensitivity. Results are dramatically improved when a threshold size of 6 mm for lymph node enlargement is used combined with an aggressive biopsy policy using fine-needle aspiration for enlarged nodes.¹²² The clear advantages of MRI over CT for T-stage assessment compare with minimal reported improvements in lymph node staging because both use similar size criteria.⁶⁶ In newly diagnosed cases, lymph node metastases, as assessed by CT, extend in a predictable and stepwise fashion from the pelvis to the abdomen. In a retrospective CT series of 500 cases, only a single case of isolated retroperitoneal nodal enlargement was reported at presentation.⁹⁷ Thus, if there is no CT evidence of lymph node enlargement in the pelvis, there is no requirement to examine the abdomen for this purpose.¹⁴⁶ Prostate cancer spreads to the external and internal iliac chains with predilection for the obturator group lying on the obturator internus muscle, then to the common iliac group and the retroperitoneum. Lymph node metastases are more likely with increasing CT T stage, and with advanced disease, nodal metastases may be large and multiple.¹⁴⁶

CT is also valuable in assessment of suspected soft tissue recurrent disease. Clinical presentations include back pain but a negative bone scan and lower limb swelling with negative sonovenographic findings. Patterns of disease differ from those at initial presentation. Retroperitoneal and upper abdominal disease may predominate, especially after pelvic radiation therapy.¹⁴⁸

About 95% of prostate cancers are adenocarcinomas and are associated with elevated PSA levels. Uncommon

cancers include transitional carcinoma from the urethra and small-cell carcinoma. Metastatic disease is commonly present at diagnosis with both small-cell and anaplastic carcinoma variants of prostate cancer; unlike the situation with prostate adenocarcinoma, metastases develop in the face of normal or minimally elevated levels of PSA.¹⁴⁰

Testicular Cancer

More than 95% of testicular cancers are germ cell tumors (GCTs), and these are the most common malignancy of men aged 15 to 34 years. The incidence is rising. However these are highly chemosensitive and radiosensitive tumors, and advances in therapy mean current prognosis is extremely good, especially in men with early-stage disease. Tumor stage, as assessed by imaging, is a key determinant of initial therapeutic options, and imaging has a major role in further management.

Malignant GCTs of the testis are divided into *seminomas* and *nonseminomatous germ cell tumors* (NSGCTs). Seminomas account for approximately 40% of GCTs and metastasize in a relatively predictable fashion via lymphatic channels. NSGCTs account for approximately 60% of testicular GCTs and have a more variable, hematogenous route of spread. Seminomas affect a slightly older population, with a mean age of 37 years, whereas NSGCTs occur in a group with a mean age of 27 years.

The serum tumor marker β -human chorionic gonadotropin (β -hCG) may be produced by both seminomas and NSGCTs, although usually only at low levels in the former. α -Fetoprotein (AFP) is elevated in up to 65% of NSGCTs but in fewer than 4% of those with seminoma. AFP is not specific to GCTs and may be elevated in patients with chronic liver disease, hepatoma, or other solid tumors. In men with tumor marker-positive NSGCTs, rising serum levels indicate metastatic disease and should prompt radiologic assessment of sites of relapse. In men with tumor marker-negative GCTs (most seminomas), radiologic examination has a key role in detection of recurrent disease.

In men with stage I NSGCTs, without adverse pathologic factors such as vascular and lymphatic invasion or greater than 50% embryonal carcinoma, a surveillance strategy is appropriate. At the other end of the spectrum, demonstration of factors known to predict poor outcome, such as para-aortic nodal disease greater than 5 cm in diameter (Fig. 44-25) or large and numerous pulmonary metastases, indicates the need for aggressive systemic therapy. The Royal Marsden Hospital staging system, widely used in the United Kingdom and Europe and adopted by the European Organization for Research and Treatment of Cancer (EORTC), takes into account both tumor volume and sites of spread (Table 44-4), as does the revised system used by both the American Joint Committee on Cancer (AJCC) and the International Union Against Cancer (Table 44-5).

CT is the most important and widely used imaging modality for staging testicular tumors. Nodal enlargement is the main criterion for assessing metastatic disease, and knowledge of patterns of spread helps with interpretation of equivocal findings. Right-sided GCTs drain primarily to the interaorticocaval, precaval, and paracaval nodes be-

Figure 44-25. Metastatic testicular teratoma. CT scan through the retroperitoneum just below the left renal vein shows a large left para-aortic node metastasis (N) from a left-sided primary.

tween L1 and L3 (Fig. 44-26), whereas left-sided tumors drain to the preaortic and para-aortic groups just below the left renal vascular pedicle (see Fig. 44-25).³³ Crossover does occur, particularly with right-sided tumors, but only in patients with more advanced disease and subsequent to ipsilateral nodal disease (see Fig. 44-26).³³ Pelvic nodal disease is uncommon in the absence of identifiable risk factors such as bulky abdominal disease (>5 cm), past history of maldescent or orchidopexy, other scrotal surgery, or invasion of tumor through the tunica vaginalis (Fig. 44-27).¹⁷⁴ Routine scanning of the pelvis in follow-up studies remains a contentious issue, but the evidence suggests that it is required only in men with the risk factors outlined earlier.^{174, 182}

In patients with advanced seminoma, disease may

Table 44-4. Royal Marsden Hospital Staging Classification for Testicular Germ Cell Tumors

Stage	Definition
I	No evidence of metastases
IM	Rising serum markers with no other evidence of metastases
II	Abdominal node metastases
A	<2 cm in diameter
B	2–5 cm in diameter
C	>5 cm in diameter
III	Supradiaphragmatic node metastases
M	Mediastinal
N	Supraclavicular cervical axillary
O	No abdominal node metastases
ABC	Node size defined as in stage II
IV	Extralymphatic metastases
	Lung:
L1	≤3 metastases
L2	>3 metastases, all < 2 cm in diameter
L3	>3 metastases, one or more > 2 cm in diameter
H+	Liver metastases
Br+	Brain metastases
Bo+	Bone metastases

Table 44-5. Tumor-Node-Metastases (TNM) Staging Classification of Testicular Tumors—1997**Primary Tumor***Extent of Primary Tumor Classified after Radical Orchiectomy (pT).*

pTX	Primary tumor cannot be assessed (if no radical orchiectomy has been performed, TX is used)
pT0	No evidence of primary tumor (e.g., histologic scar in testis)
pTis	Intratubular germ cell neoplasia (carcinoma in situ)
pT1	Tumor limited to testis and epididymis without vascular/lymphatic invasion; tumor may invade into the tunica albuginea but not tunica vaginalis
pT2	Tumor limited to testis and epididymis with vascular/lymphatic invasion, or tumor extending through tunica albuginea with involvement of tunica vaginalis
pT3	Tumor invades spermatic cord with or without vascular/lymphatic invasion
pT4	Tumor invades scrotum with or without vascular/lymphatic invasion

Regional Lymph Nodes*Clinical Involvement*

NX	Regional nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis with a lymph node mass ≤ 2 cm in greatest dimension or multiple lymph nodes none > 2 cm in greatest dimension
N2	Metastasis with a lymph node mass > 2 cm but ≤ 5 cm in greatest dimension
N3	Metastasis with a lymph node mass > 5 cm in greatest dimension

Pathologic Involvement

pN0	No regional lymph node metastases
pN1	Metastasis with a lymph node mass ≤ 2 cm in greatest dimension and five or fewer positive nodes, none > 2 cm in greatest dimension
pN2	Metastasis with a lymph node mass > 2 cm but ≤ 5 cm in greatest dimension; or more than 5 nodes positive, none > 5 cm; or evidence of extranodal tumor
pN3	Metastasis with a lymph node mass > 5 cm in greatest dimension

Distant Metastasis

MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
M1a	Nonregional lymph node or pulmonary metastasis
M1b	Distant metastasis other than to nonregional lymph nodes and lungs

spread to contiguous nodal groups in the mediastinum. Pulmonary metastases without such adenopathy are rare. Conversely, mediastinal disease from NSGCTs tends to be more unpredictable and lung metastases are relatively more common.^{179, 181} Such patterns of disease spread have implications for follow-up and surveillance protocols involving the use of thoracic CT versus chest radiography.¹⁷³

A continual challenge in radiology is to identify metastatic disease in nonenlarged nodes. Lymphangiography is the only modality that can demonstrate nodal internal architecture; however, it has its own inherent limitations, including an inability to demonstrate nodes above the level of the second lumbar vertebra or outside the retroperitoneal chain. The most lateral of the testicular drainage groups, the *echelon nodes*, are not opacified following pedal injections.¹⁰² The extent of disease beyond the boundary of the node when capsular breach has been demonstrated can only be inferred, and its true extent cannot be assessed. Furthermore, the examinations are difficult to perform, time-consuming, and unpleasant for the patient. With con-

Figure 44-26. Metastatic testicular teratoma. CT scan through the retroperitoneum shows cystic nodal metastases from a right-sided primary. In addition to the precaval metastases (arrow), there is crossover into left-sided preaortic and para-aortic nodes (arrowheads).

tinuing improvements in CT technology, the declining use of lymphangiography means that expertise is being lost and it is now rarely performed.

Size remains the only criterion for judging nodal involvement by GCTs, but familiarity with patterns of disease behavior allows radiologists to highlight nonenlarged nodes, which by virtue of their position in relation to other sites of disease should be regarded as suspicious for involvement. Appearance and attenuation values of nodes may also be helpful. Seminomatous metastases are generally of soft tissue density, whereas NSGCTs may be of low attenuation or frankly cystic (see Fig. 44-26).

Staging and follow-up examinations are generally carried out without IV contrast enhancement, and close attention to bowel opacification by oral contrast agent is re-

Figure 44-27. Tumor in an undescended testis. CT scan through the pelvis shows a large cystic-necrotic mass (M) invading the left iliopsoas muscles. Excision revealed testicular teratoma within a nodal mass.

quired to avoid overestimating abdominal disease. An IV contrast agent should be used for problem solving in the retroperitoneum when distinction of adenopathy from possible vascular anomalies of the inferior vena cava, renal vessels, or gonadal and lumbar veins is not readily apparent from the unenhanced images.

Residual masses are a relatively common finding in GCT patients treated initially with chemotherapy for advanced-stage disease. With NSGCTs, residual masses may be predominantly cystic and represent residual malignancy, mature or immature teratoma, or necrosis and fibrosis.¹⁵² Enlarging retroperitoneal, mediastinal, or pulmonary masses in these patients with negative serum tumor markers after chemotherapy frequently represents mature teratoma.^{98, 123} In patients with NSGCTs, because CT cannot reliably exclude malignancy, residual masses larger than 1 cm are resected.^{62, 87}

Because many such retroperitoneal and mediastinal masses are intimately related to major vascular structures, preoperative limited, thin-section contrast-enhanced CT scans with MPR can aid surgical planning. The approach to seminomatous residual masses is not as clear-cut. Such abnormal areas often contain necrosis and fibrosis rather than viable tumor, and resection is often difficult and incomplete. The CT appearance alone may guide management strategy for seminoma, with the suggestion that residual masses smaller than 3 cm and poorly defined residual masses larger than 3 cm should undergo surveillance, whereas well-defined masses larger than 3 cm should be resected.¹²⁹ Gallium scanning in residual seminoma disease appears to be of minimal value.¹⁷⁰ However, there may be potential for FDG-PET (fluorodeoxyglucose-positron emission tomography) scanning in this area of clinical and radiologic uncertainty.

The Undescended Testis

The testis may be cryptorchid, lying anywhere along the path of normal descent between the renal hilum and scrotal sac. It may be retractile, ectopic, atrophic, or absent. Approximately 80% of impalpable testes lie in the inguinal canal and 20% are within the abdomen. Testicular absence occurs in about 4% of cases of impalpable testes. Complications of undescended testes include malignancy (see Fig. 44-27), infertility, torsion, sequelae associated with inguinal hernias, and the psychological impact on patients.

Orchidopexy is the desired treatment in patients older than 1 year of age because, until that age, spontaneous descent can occur. After puberty, because of the increased risk of malignant transformation, orchidectomy is performed. In children, surgery is usually performed and thus preoperative imaging is not routinely required. In adults, however, the cryptorchid testis warrants treatment, and in the 20% that are impalpable, imaging may play a role in locating the testis and in guiding surgical intervention.

Ultrasonography is often the initial investigative modality and can locate cryptorchid testes in the inguinal canal and between the external ring and scrotal neck. It can also detect an atrophic testis or an ectopic lie, such as in the superficial inguinal pouch or the contralateral hemiscrotum. Its limitation is in the assessment of testes that lie proximal to the internal inguinal ring.

The inherent soft tissue contrast of MRI and the lack of ionizing radiation make it the modality of choice for investigating patients with negative ultrasonographic findings.⁴⁵ The testis can be accurately located in the abdomen, pelvis, or inguinal region, and intratesticular lesions can be demonstrated within large cryptorchid testes that have become malignant.

CT demonstrates the undescended testis as an ovoid mass of soft tissue density, usually 2 cm or smaller in size, along the expected course of descent.^{90, 180} Large masses should raise suspicion for malignant change (see Fig. 44-27).

For assessment of suspected intra-abdominal undescended testis, CT examination with full oral and IV contrast agents increases the ability to distinguish the testis from lymph nodes, vessels or bowel loops. Currently, laparoscopy is the preferred diagnostic and therapeutic procedure in adults.

Cervical Cancer

Invasive cervical cancer is the third most common gynecologic malignancy in the United Kingdom and the United States, with a peak incidence between ages 35 and 50 years. Most women present with vaginal bleeding. The clinical examination is frequently diagnostic, and colposcopy and biopsy establish the histologic diagnosis.

Most cervical tumors are of squamous cell type arising from the squamocolumnar junction near the external os. The remainder are adenocarcinomas or adenosquamous carcinomas. In older women, the external os migrates upward into the endocervical canal, and tumors arising here tend to expand the canal and extend upward into the uterine body. In younger women, tumors arising on the ectocervix tend to be more polypoidal and exophytic.

In most cases, cervical intraepithelial neoplasia (CIN) is known to precede invasive squamous disease, and detection of this condition and of early invasive disease by cervical screening programs has led to a reduction in overall mortality rates. CIN is radiologically occult, and therefore diagnostic imaging is reserved for histologically proven invasive disease.

Cervical cancer spreads locally into the parametrial tissues and the supporting ligaments around the uterus. Inferior spread onto the vagina occurs and with advancing disease involvement of the pelvic sidewalls, bladder, and rectum can be seen. Nodal spread initially is to parametrial, obturator, and presacral nodes, followed by internal, external, and common iliac groups. Later retroperitoneal and supraclavicular nodal disease may occur. Hematogenous involvement of liver, lung, and bone occurs in advanced disease.

Radical surgery and radiation therapy are treatment options for stages IA, IB, and IIA disease (Table 44-6); radiation therapy is the treatment of choice for more advanced stages IIB to IVB, with chemotherapy an option for those with distant metastases. The prognosis in cervical carcinoma is closely linked to tumor stage and volume.^{64, 103} Although nodal status is not included in the International Federation of Obstetrics and Gynecology (FIGO) staging system, it has been found to have a significant prognostic

Table 44–6. International Federation of Obstetrics and Gynecology (FIGO) Staging of Carcinoma of the Uterine Cervix

Stage	Summary of FIGO Classification
0	Carcinoma in situ (preinvasive)
I	Carcinoma confined to the cervix; extension to corpus should be disregarded
IA	Preclinical carcinomas, i.e., those diagnosed only by microscopy
IA1	Stromal invasion ≤ 3.0 mm in depth and < 7.0 mm in horizontal spread
IA2	Lesions detected microscopically that can be measured. The upper limit of the measurement should not show a depth of invasion > 5 mm taken from the base of the epithelium, either surface or glandular, from which it originates, and a second dimension, the horizontal spread, must not exceed 7 mm. Larger lesions should be staged as IB
IB	Lesions of greater dimensions than stage IA2 whether seen clinically or not. Performed space involvement should not alter the staging but should be specifically recorded so as to determine whether it should affect treatment decisions in the future
IB1	Clinically visible lesion ≤ 4 cm in greatest dimension
IB2	Clinically visible lesion > 4 cm in greatest dimension
II	Carcinoma extending beyond the cervix but no extension onto the wall. The carcinoma involves the vagina but not the lower third
IIA	No obvious parametrial involvement
IIB	Obvious parametrial involvement
III	Carcinoma extension onto the pelvic wall. On rectal examination, there is no cancer-free space between the tumor and the pelvic wall. The tumor involves the lower third of the vagina. All cases with hydronephrosis or nonfunctioning kidney
IIIA	No extension to the pelvic wall
IIIB	Extension onto the pelvic wall and/or hydronephrosis or nonfunctioning kidney
IV	Carcinoma extension beyond the true pelvis or clinical involvement of the mucosa of the bladder or rectum. A bullous edema, as such, does not permit a case to be staged as stage IV
IVA	Spread of growth to adjacent organs
IVB	Spread to distant organs

impact on outcome in patients treated with radiation therapy.¹⁵⁹

The aim of cross-sectional imaging is accurate local staging to identify patients who are candidates for radical surgery and to demonstrate the extent of disease in patients who are not. MRI is the modality of choice for local tumor staging. It is accurate and cost-effective in assessment of patients with invasive disease when it is used as an adjunct to clinical evaluation. It is not appropriate in patients with *stage IA* or obviously advanced disease. However, the inherent inaccuracy of clinical staging and the increased incidence of lymphadenopathy with increasing tumor bulk mean that it is recommended in those with suspected *stage IB* disease when the tumor is large (> 2 cm) or within the endocervical canal and in patients with suspected parametrial extension.

MRI is significantly better than CT for local staging; therefore, the main role of CT is in more advanced disease.¹⁵³ The cervix may appear enlarged with an irregular contour, and enhancement may be inhomogeneous in the presence of areas of necrosis and ulceration. Uterine enlargement and fluid collections within the endometrial cav-

ity are often seen when tumor obstructs the endocervical canal. Poorly defined lateral cervical margins, stranding of the parametrial fat, and an eccentric parametrial soft tissue mass have been described as CT criteria for parametrial invasion (Fig. 44–28). However, these are subject to considerable error and overstaging because hyperemia and parametritis can cause identical appearances. Effacement of fat planes around the ureter is a more reliable CT sign but is usually found only when gross parametrial extension has occurred.⁶⁷ Extension of abnormal tissue to or within a couple of millimeters of the pelvic sidewall characterizes stage IIIB disease. These cases often show associated renal tract compromise, and CT can elegantly demonstrate hydronephrosis and hydroureter. Secondary signs of renal obstruction, such as unilateral delayed renal cortical enhancement and cortical loss, can also be seen.

Although CT can demonstrate loss of local fat planes, bladder and rectal wall thickening, and frank intraluminal disease, the multiplanar ability and intrinsic soft tissue contrast of MRI make it more sensitive for detecting local organ invasion (stage IVA disease).⁸² CT is widely used in a diagnostic capacity in both advanced primary and recurrent disease as described. However, another major role is that of therapy planning in those women who are to undergo radiation therapy either as primary treatment due to advanced stage disease or co-morbidity factors that preclude radical surgery, or as salvage treatment for recurrence. Information regarding nodal disease is vital for planning of radiation fields and for deciding between radical and palliative treatment.

One of the major roles of CT in the management of patients with clinically suspected advanced stage cervical carcinoma is assessment of lymphadenopathy. Knowledge of the probable pattern of disease spread aids in this task; however, size remains the only CT criterion available for predicting nodal involvement. Attenuation of nodes may also be helpful, as with testicular tumors. Nodal metastases from squamous cervical carcinomas may have low attenuation centers reflecting necrosis (Fig. 44–29).

In the detection of pelvic and retroperitoneal lymph node metastases, CT and MRI have a similar overall accuracy ($\sim 86\%$).¹⁵³ Lymphangiography is rarely performed now, but the use of ultra-small superparamagnetic iron oxide (SPIO) as an MR lymphangiographic contrast agent may be a useful tool in the future for further characterization of nodes that are indeterminate by size criterion alone.⁵⁸

CT is widely used to investigate suspected recurrent disease (Fig. 44–30). In women treated initially with surgery, CT is accurate for demonstrating central pelvic recurrence, perineal disease, and nodal masses. When the primary treatment has been radical radiation therapy, recurrent masses and invasion of local structures as well as treatment complications such as fistulas can be assessed.

A persisting problem with CT is the differentiation of recurrent tumor from radiation therapy or postsurgical fibrosis.^{80, 169} Although it had initially been hoped that MRI would be helpful in this situation, MRI also has its limitations, since the signal characteristics of radiation-induced fibrosis can be extremely variable and both recurrent disease and radiation fibrosis can show contrast en-

Figure 44-28. Stage T4 cervical cancer. CT scan through the cervix. A, The cervix (C) is expanded by a heterogeneous enhancing cancer that shows a thin, intact capsule (*arrowheads*). B, At a lower level, invasion of the anterior wall of the rectum (R) and parametrial invasion (*arrows*) are seen.

hancement. The role of PET scanning in this situation is being assessed.¹⁵⁴

The cervix is sometimes secondarily involved by non-Hodgkin's lymphoma (NHL) in the context of widely disseminated disease. However, primary lymphoma of the cervix is rare, accounting for approximately 1% of extranodal NHL. On CT scans, the cervix appears diffusely enlarged by an enhancing soft tissue mass (Fig. 44-31). Lymphadenopathy may be absent in primary cervical lymphoma, in contrast to secondary disease.¹¹² Internal heterogeneity may reflect areas of necrosis. The histologic diagnosis is vital in such cases because the treatment and prognosis of stage IE NHL are vastly different from those of cervical carcinoma.⁸⁴

Figure 44-29. Metastatic cervical cancer. CT scan through the lower retroperitoneum shows a left para-aortic nodal metastasis (N) from cervical cancer having an irregular enhancing margin (*arrowheads*) and central necrosis. Such margins predict extra-nodal tumor extension.

Uterine Tumors

Benign Uterine Tumors

Uterine leiomyomata are common benign uterine neoplasms, occurring in 20% to 40% of women. Often found incidentally on CT, they may present as a palpable abdominal mass, may be associated with pain or bleeding, or may cause symptoms of compression related to the bladder or rectum. They usually appear as homogeneous soft tissue attenuation masses causing uterine enlargement but often have a characteristic "whorled" appearance (Fig. 44-32). The presence of necrosis or degeneration can give a low attenuation appearance. Leiomyomata therefore may be hypodense, isodense, or hyperdense relative to normal myometrium on contrast-enhanced CT.

Calcification is not uncommon, occurring in approxi-

Figure 44-30. Recurrent cervical cancer. CT scan shows a central pelvic tumor (T) after hysterectomy involving the anterior rectum (R) and posterior bladder wall (*arrows*) and extending to both pelvic sidewalls on this delayed excretory-phase image. Note the lymphadenectomy clip in the left obturator fossa.

Figure 44-31. Cervical lymphoma. CT scan shows a homogeneous enhancing mass expanding the cervix (C).

mately 10%, and coarse dystrophic calcification is a relatively specific feature.^{24, 78} Leiomyomata may lie in a subserosal location, causing a lobulated uterine contour or be submucosal, distorting the endometrial cavity and then becoming indistinguishable from endometrial tumors.¹³⁷ Some leiomyomata are pedunculated and mimic adnexal masses. It is not always possible to ascertain the organ of origin of such lesions, especially if noncalcified, and multiplanar MRI with its inherent tissue contrast showing zonal anatomy can help with such problem solving.

Uterine Cancer

Endometrial carcinoma is a common gynecologic malignancy that primarily affects postmenopausal women, who usually present with bleeding. Approximately 75% of patients have stage I disease at presentation (Table 44-7). Histologic type and grade of tumor, depth of myometrial invasion, cervical involvement, and the presence of nodal

Figure 44-32. Large uterine leiomyoma. CT scan at the iliac crest shows a typical heterogeneous enhancement pattern of a giant leiomyoma (L) of the uterus.

Table 44-7. International Federation of Obstetrics and Gynecology (FIGO) Classification of Carcinoma of the Uterine Corpus

Stage	Summary of FIGO Classification
IA	Tumor confined to the endometrium
IB	Invasion of less than half of the depth of the myometrium
IC	Invasion of more than half of the depth of the myometrium
IIA	Extension to the cervix, endocervical glands only involved
IIB	Invasion of the cervical stroma
IIIA	Invasion of the uterine serosa, or adnexa, and/or positive peritoneal cytology
IIIB	Vaginal involvement (direct extension or metastasis)
IIIC	Pelvic and/or para-aortic lymph node metastases
IVA	Invasion of bladder and/or bowel mucosa
IVB	Distant metastases, including extrapelvic lymph node metastases

disease influence prognosis and treatment strategies. Surgery is the treatment of choice in patients with disease confined to the myometrium. Most endometrial cancers are well-differentiated adenocarcinomas, and surgical treatment for organ-confined disease has a 10-year survival of approximately 80%. Most of these patients are managed on clinical grounds alone without imaging other than transvaginal ultrasonography.

The prognosis is not as optimistic for clear cell and papillary serous carcinomas of the endometrium, and these tumor types correlate with higher incidence of lymph node metastases (see Fig. 44-17). The likelihood of nodal metastases also increases with depth of myometrial invasion.¹² Therefore, radiologic staging is appropriate in patients with high-grade or other adverse histology, clinical suspicion for advanced disease, or where co-morbidity factors make the patient a poor operative risk.

MRI, if available, is the imaging modality of choice for assessing depth of myometrial invasion and cervical involvement.^{83, 142} Knowledge of such disease extent influences the type of hysterectomy and extent of lymphadenectomy performed. The presence of cervical involvement is important for planning brachytherapy. Demonstration of parametrial disease implies that nonoperative treatment is the appropriate management strategy.

When MRI is available, there is virtually no role for CT in the diagnosis and assessment of early-stage endometrial carcinoma.^{28, 60} CT does, however, affect clinical management in women with more advanced-stage disease and is accurate for demonstrating disease extension to the pelvic sidewalls, pelvic and retroperitoneal nodal enlargement, and distant metastases to the liver and lungs.

Endometrial tumors appear as a hypodense or enhancing mass within the uterine cavity or within the myometrium on contrast-enhanced CT (Fig. 44-33). It may be difficult to distinguish tumor from coexistent leiomyomata and to assess disease in the atrophic postmenopausal uterus. Cervical involvement may cause a bulky cervix and a distended uterine cavity. In women with more advanced disease, the CT appearance of parametrial, adnexal, pelvic sidewall, and nodal involvement is similar to that seen with primary cervical carcinoma. Adnexal disease may also reflect coincident endometrioid ovarian cancer. The appearance and pattern of recurrent disease are similar to

Figure 44-33. Endometrial cancer. CT scan through the uterus shows a distended endometrial cavity (E) containing enhancing tumor (arrow).

those in advanced primary disease, but peritoneal recurrence may also be seen.

Gestational trophoblastic disease (GTD) results from abnormal proliferation of pregnancy-associated trophoblastic tissue and has a potential for malignant transformation. It includes benign partial and complete hydatidiform moles, malignant invasive moles, and choriocarcinoma. The clinical presentation is marked by vaginal bleeding, hypertension, hyperemesis, a large-for-dates uterus, and an inappropriately elevated serum β -hCG level. Ultrasonography demonstrates the characteristic appearance of a molar pregnancy with cystic and solid tissue filling the uterus. Ultrasonography can also identify the relatively rare occurrence of a molar pregnancy coexisting with a separate normal gestation. This is presumed to occur as a result of molar transformation in one of a twin gestation. Its main role, however, is to exclude a normal intrauterine pregnancy.

Hydatidiform moles are treated with dilatation and curettage (D&C). This is usually a curative procedure, and serum β -hCG levels subsequently return to normal. Persistent or recurrent disease occurs in 15% to 20%, and this

diagnosis is confirmed by failure of serum markers to normalize. Invasive moles penetrate deep into the myometrium and may penetrate the parametria, broad ligaments, peritoneum, or vaginal vault. They are locally invasive but rarely metastasize.

Choriocarcinoma is a malignant tumor of the chorionic epithelium; absence of villous structures that give noninvasive and invasive moles their characteristic appearance is an important diagnostic feature. Metastatic disease occurs early with choriocarcinoma and is generally blood-borne. Pulmonary, hepatic, cerebral, and vaginal metastases are common.

Determining the serum β -hCG level is the most accurate way to detect persistent GTD and to monitor its treatment. Ultrasonography cannot always distinguish between noninvasive and invasive disease in the absence of gross tumor spread, and CT is used to image persistent local pelvic and metastatic GTD (Fig. 44-34).

Uterine invasive mole or choriocarcinoma typically appears as eccentric hypodense foci in the myometrium or endometrial cavity on contrast-enhanced CT.^{54, 115, 135} CT can demonstrate disease that has invaded the broad ligament, parametria, and pelvic fascia and muscles.^{31, 135} It can also evaluate hepatic, pulmonary, and cerebral metastases. Solid-organ secondary deposits are classically hypervascular (see Fig. 44-41). Theca-lutein cysts are sometimes found in patients with GTD and are thought to be due to overstimulation by the large amounts of β -hCG.²³ They are elegantly demonstrated by both CT and ultrasonography as multiloculated cysts that are often bilateral.

Leiomyosarcomas are rare uterine malignancies and may arise de novo or may occur as a result of malignant transformation. Distinction between degeneration and malignant change is not possible on morphologic grounds alone, and in the absence of any secondary signs of malignancy, imaging has a limited role in the assessment of such tumors. Mixed müllerian sarcomas are the more common uterine sarcoma. They tend to occur in postmenopausal women, have a more aggressive nature, and often present with a bulky, locally invasive primary and metastatic disease. The imaging appearance is not specific, but the size of the lesion may suggest its nature, and scanning the chest and abdomen allows assessment of distant disease spread.

Figure 44-34. Gestational trophoblastic disease. A, CT scan through uterus shows a contrast-enhanced tumor (arrows) filling a dilated endometrial cavity and an intact myometrium. B, Dynamic CT scan through the liver shows a hypervascular metastasis (arrows).

Ovarian Tumors

Ultrasonography is the investigative modality of choice in women when a pelvic mass is suspected. In most cases, ultrasonography can characterize the mass as either uterine or ovarian and suggests its malignant potential on the basis of morphologic features of the mass and the presence of ascites or visceral metastases. Symptomatic ovarian masses are usually removed. For a benign mass, excision alone suffices; for a malignant mass, major cytoreductive surgery may be required.

CT has a central role in the management of ovarian cancer but is infrequently used for assessment of benign gynecologic masses. It is essential, however, that the CT appearances of ovarian masses be recognized because these lesions may be discovered incidentally on pelvic CT assessment.^{55, 137} Further, CT is increasingly being used to investigate the acute abdomen, and one needs to decide whether such a mass is relevant to the presenting complaint and, if not, whether further investigation is indicated.

Benign Ovarian Masses

The CT features of a simple ovarian cyst are those of a benign cyst at any site: a homogeneous, unilocular water-density mass with smooth, thin walls and no other internal contents.^{55, 138} These are frequently functional cysts that usually resolve spontaneously and this can be confirmed by ultrasonographic follow-up after 2 to 3 months, without further exposure to ionizing radiation. Simple ovarian cysts are increasingly detected as incidental findings in postmenopausal women.

Criteria for diagnosis are a unilocular cyst with no internal components of no more than 5 cm in size in a woman without ascites.⁵³ Stability in such cysts should again be confirmed with follow-up ultrasonography. Congenital cysts of the lower urogenital tract and a variety of acquired fluid-containing structures can mimic a simple ovarian cyst, including unopacified bowel, bladder diverticulum, a peritoneal inclusion cyst, and focally entrapped fluid following pelvic inflammation or surgery.⁶³ A purely cystic ovarian cancer is rare.⁴⁷

There is a wide differential diagnosis for a complex cystic adnexal mass, including a number of benign conditions: ovarian neoplasms such as cystadenoma and cystic teratoma and more common conditions, such as endometriosis and pelvic inflammatory disease with hydrosalpinx/pyosalpinx formation. CT criteria for complex adnexal masses include wall (mural) thickening and irregularity, heterogeneous density including calcifications, irregular or thick septa, internal or mural nodules, and outer contour irregularity. These are, unfortunately, common not only to the earlier benign conditions but also to borderline and invasive malignancies (Fig. 44–35). The presence of ascites suggests malignancy, but complicated benign disease can also result in ascites or localized fluid collections as a result of hemorrhage, infection, or torsion. After torsion, an ovarian mass may show poor contrast enhancement and irregular margins.

Although suspected endometriomas and tubo-ovarian abscesses are usually evaluated by ultrasonography, they

Figure 44–35. Borderline mucinous ovarian cancer. CT scan through a complex right ovarian mass (M) shows thick internal septa (arrow) and wall irregularities (arrowhead).

may be detected on CT examinations performed to investigate pelvic pain and fever. These are lesions within the differential diagnosis for appendicitis and urinary colic, both of which are increasingly investigated by CT emergently. There are varying reports of the CT appearances of endometriomas, some indicating their nonspecific nature and others identifying small focal blood clots adjacent to the inner wall in 15% of endometriomas.^{22, 40} Bilateral thick-walled, multilocular cysts or mixed cystic-solid masses may be present (Fig. 44–36). There may also be evidence of coincident adenomyosis with uterine enlargement. MRI may be diagnostic by showing contained blood products within suspected endometriomas.¹¹⁴

The acute tubo-ovarian abscess is the most severe complication of pelvic inflammatory disease. The CT features may reflect either or both of the two components: (1) a tubular fluid-density mass, the hydrosalpinx or pyosalpinx; or (2) the septated thick-walled adnexal cyst, the ovarian abscess (Fig. 44–37). Pelvic inflammatory changes may obscure the fat planes between pelvic organs and can result

Figure 44–36. Endometriosis. CT scan through bilateral thick-walled giant ovarian endometriomas (E) in a 22-year-old woman with intermittent abdominal pain.

Figure 44-37. Pelvic inflammatory disease. CT scan through the pelvis shows a thick-walled multilocular right tubo-ovarian abscess (A). The uterus (U) contains a contraceptive device. Note also blurring of pelvic fat planes and loculi of pus (arrows). There is narrowing of both the rectosigmoid junction and the pelvic small bowel (arrowheads).

in thickened uterosacral ligaments and reactive pelvic and para-aortic lymphadenopathy. Other secondary effects include small-bowel and rectosigmoid involvement (see Fig. 44-37), ureteral dilatation, and gonadal vein thrombosis.^{36, 178} Primary treatment is usually with antibiotic therapy, but intervention may be required and CT-guided abscess drainage offers a nonoperative option. CT drainage is associated with an 88% to 94% success rate.^{25, 160}

Ovarian cystadenomas are usually serous or mucinous. They may occasionally be purely cystic and unilocular (Fig. 44-38), but more frequently cystadenomas are complex multilocular lesions showing varying degrees of mural abnormality and heterogeneous density, including calcifications and septation.¹³⁸ Mucinous cystadenomas may contain high-density loculi of mucin, but such high-density in cystadenomas may also result from hemorrhage. These

Figure 44-38. Mucinous cystadenoma of the ovary. CT scan through the purely cystic abdominal mass (C) in an asymptomatic 66-year-old woman with a palpable mass.

high-density foci may mimic a solid tumor component. Complexity in mucinous cystadenomas may make distinction from a borderline or stage I malignant cystadenocarcinoma impossible (see Fig. 44-35).^{21, 47}

Mature cystic teratoma (*dermoid tumor*) may have various CT appearances, depending on its contents. The diagnosis may be made incidentally on plain radiographs of the abdomen or pelvis or with ultrasonography. When the nature of an echogenic adnexal mass detected by ultrasonography is uncertain, either CT or MRI may be performed for a confident diagnosis.¹⁵¹ CT findings include a mixture of low-density areas due to fat or oil, high density from dental elements or cartilaginous calcifications, a fat-fluid level, or a dermoid plug (Fig. 44-39).^{20, 44} Alternatively, benign teratomas may appear as cystic lesions. Malignant teratomas are rare. The presence of an irregular solid component larger than 5 cm in diameter suggests malignancy (Fig. 44-40).²⁰

Although the presence of a solid element is highly suggestive of malignancy, several benign solid tumors, including fibroma and fibrothecoma (Brenner's tumor), are uniformly solid and smoothly margined.¹³⁸ Ovarian fibroma may be associated with large-volume ascites and pleural effusion (*Meig's syndrome*). A pedunculated uterine leiomyoma may mimic a solid or cystic ovarian mass and may present as an emergency following torsion (Fig. 44-41).

Early studies have shown that CT was superior to ultrasonography in distinguishing between benign and malignant ovarian epithelial tumors and that CT and MRI had an equivalent overall accuracy in evaluating epithelial tumors of the ovary.^{21, 52} The Radiology Diagnostic Oncology Group (RDOG) study, which compared CT with both Doppler ultrasonography and MRI in the assessment of pelvic masses, showed that MRI was slightly better than CT and significantly better than Doppler ultrasonography in assessment of the ovaries and adnexa.⁸⁸ All three modalities were equivalent in staging of malignant ovarian masses, given that ascites was indicative of peritoneal dissemination in most cases.

Figure 44-39. Bilateral benign teratomas. *Left*, CT scan shows a typical benign teratoma containing fat (F) and dental elements (arrow). *Right*, A pure cystic teratoma (C) is seen.

Figure 44-40. Malignant teratoma. CT scan through pelvic mass that contains fluid (F) and a complex solid component (S) that contains small areas of fat and calcification indicating malignancy.

Ovarian Cancer

Ovarian cancer is the leading cause of death from female genital tract malignancy and accounts for about 4% of all female cancers. Women with ovarian cancer typically present with advanced-stage disease, leading to elevation in the serum marker carcinoembryonic antigen 125 (CEA-125). Epithelial ovarian cancer (adenocarcinoma) is a disease of older women. In younger women, ovarian cancer is more commonly due to GCTs, which may produce elevated serum AFP and β -HCG, or to sex cord stromal tumors. Although there are various subtypes of ovarian adenocarcinoma, the prognosis is independent of these and is principally determined by stage at diagnosis (Table 44-8).

Management for all subtypes is similar, and the recommended initial treatment for epithelial ovarian cancer is

Figure 44-41. Solid adnexal mass. CT scan through the pelvis of a woman with acute abdominal pain and a lower abdominal solid mass (M). This image shows a rim of fluid (arrows) and a central solid element with lesser enhancement than muscle. At surgery, an infarcted pedunculated uterine leiomyoma was discovered.

Table 44-8. International Federation of Obstetrics and Gynecology (FIGO) Staging Classification for Ovarian Cancer

Stage	Characteristics
I	Growth limited to the ovaries
IA	Growth limited to one ovary; no malignant ascites; negative peritoneal cytology finding; no tumor on the external surface; capsule intact
IB	Growth limited to both ovaries; no malignant ascites; negative peritoneal cytology finding; no tumor on the external surface; capsule intact
IC	Tumor either stage IA or IB, but with tumor on the surface of one or both ovaries; or with capsule ruptured; or with ascites present containing malignant cells; or with positive peritoneal washings
II	Growth involving one or both ovaries with pelvic extension
IIA	Extension or metastasis to the uterus, tubes, or both
IIB	Extension to the pelvic tissues
IIC	Tumor either stage IIA or IIB, but with tumor on surface of one or both ovaries; or with capsule(s) ruptured; or with ascites present containing malignant cells; or with positive peritoneal washings
III	Tumor involving one or both ovaries with peritoneal implants outside the pelvis or a positive finding in retroperitoneal or inguinal glands; superficial liver metastases; tumor limited to the true pelvis but with histologically proven malignant extension to small bowel or omentum
IIIA	Tumor grossly limited to the true pelvis with unaffected nodes but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces
IIIB	Tumor involving one or both ovaries with histologically confirmed implants on abdominoperitoneal surfaces, none > 2 cm in diameter, nodes unaffected
IIIC	Abdominal implants > 2 cm in diameter or unaffected retroperitoneal or inguinal nodes
IV	Growth involving one or both ovaries with distant metastases; if pleural effusion is present, there must be a positive cytology finding; parenchymal liver disease

debulking surgery. For the minority of women with disease apparently confined to the ovary, this may be curative. For the majority of women with peritoneal dissemination of tumor, treatment is with cytoreductive surgery, with the goal to leave deposits no more than 1 cm in diameter. The extent of residual disease is also a prognostic factor. Surgery is the definitive staging procedure. Biopsy specimens of peritoneal surfaces and lymph nodes are obtained, and the ovaries, uterus, and infracolic omentum are removed. For locally or distantly metastatic ovarian cancer, stages IC to IV, surgery is followed by chemotherapy.

When a suspected ovarian adenocarcinoma must be evaluated preoperatively, CT is the imaging modality of choice.^{1, 76, 176} It can replace urography and barium studies for assessment of hollow organ involvement and in most cases accurately determines tumor extent. CT is inferior to surgical staging in detecting tiny peritoneal, omental, and mesenteric nodules, but this is not its role. Rather, in the presence of bulky disease, CT predicts the probable success of cytoreductive surgery.¹¹¹ CT also indicates when the gynecologist may require assistance from other surgical colleagues to achieve effective debulking (e.g., when the ureters, pelvic small bowel, or colon is involved). Bulky disease in the supracolic compartment around the spleen and stomach, suprarenal lymph nodes, subdiaphragmatic recesses, and parenchyma of the liver is usually beyond the scope of surgery.

Figure 44-42. Omental biopsy. CT-guided biopsy of the omental cake (C) by means of an 18-gauge cutting needle. The patient had been considered unfit for primary surgery. Biopsy revealed serous papillary adenocarcinoma of müllerian type, consistent with ovarian cancer.

In one study, MRI was superior to CT in ovarian cancer staging in assessing pelvic disease but not abdominal disease.⁴³ In that study, CT was better at predicting nonresectability. CT-guided biopsy offers an alternative to surgery to provide a definitive histologic diagnosis in women with inoperable disease (Fig. 44-42).¹⁴⁹ There is current interest in neoadjuvant chemotherapy followed by interval debulking surgery for these women.

The CT features of epithelial ovarian cancer are those of the primary tumor and those of its metastatic spread. Several primary tumor patterns overlap with those of complex benign lesions: a multiloculated cyst with thick walls or septations and some solid components (see Fig. 44-35), a combined cystic and solid mass (Fig. 44-43), and a predominantly solid mass. Calcifications and contrast enhancement may be present in the cyst wall or within solid tumor components. There is an overlap in the CT features of the epithelial subtypes, but there are some more specific findings: serous cancers are the most common and may

Figure 44-43. Bilateral ovarian cancers. CT scan through the uterus (U) shows solid right and cystic and solid left ovarian cancers (O) surrounded by ascites.

show heavy psammomatous calcification; ruptured or metastatic mucinous tumors result in a pseudomyxoma appearance; endometrioid cancers may coexist with uterine cancers (Fig. 44-44).

The CT appearance of ovarian metastases may be indistinguishable from that of primary ovarian cancer. Both conditions may produce bilateral masses. In further analysis of the RDOG study, the only factor favoring primary ovarian cancer was multilocularity, as shown by ultrasonography or MRI. This was not a significant feature for CT.¹⁴ The stomach, colon, appendix, and pancreas are within the examination volume and should be inspected as potential primary cancer sites within the abdomen.^{27, 107}

Breast cancer and ovarian cancer are now recognized to be linked genetically. In women with a history of a primary tumor whose metastases may exactly mimic primary ovarian cancer (e.g., breast and colon), a definite histologic diagnosis is required because debulking surgery is inappropriate for such metastatic disease and chemotherapeutic regimens differ. CT-guided peritoneal or adnexal biopsy suffices in this situation (see Fig. 44-42).¹⁴⁹

Primary ovarian cancers are most frequently found in the adnexal region or pouch of Douglas (rectouterine recess), displacing the uterus, bladder, and rectum. The mass usually enlarges into the abdomen to lie above the bladder, displacing pelvic small bowel. Metastatic spread is predominantly via the peritoneal cavity, usually with ascites but also via lymphatics to the pelvic and para-aortic groups, and by hematogenous spread to the liver. Patterns of spread identified within the pelvis (*stage II*) by CT are involvement of small and large bowel, the pelvic sidewall with encasement of the iliac veins leading to thrombosis of the pelvic ureter with resultant hydronephrosis. However, hydronephrosis is more commonly due to simple mass effect on the pelvic ureter.

Metastatic spread to the abdomen (*stage III*) may manifest as peritoneal and mesenteric masses and omental

Figure 44-44. Endometrioid cancer. CT scan through the pelvis shows coincident tumors of the endometrium (E) and left ovary (O).

Figure 44-45. Stage IIIC ovarian cancer. CT scan through the liver and spleen shows multiple surface deposits (arrows). A surface tumor within the cleft of the falciform ligament (F) mimics parenchymal metastasis.

cakes. Spread occurs to all peritoneal surfaces, recesses, and reflections and particularly the undersurfaces of the diaphragm. Involvement of the surface of the liver and spleen is classified as stage III (Fig. 44-45). Surface tumor within the cleft of the falciform ligament may mimic parenchymal metastasis (see Fig. 44-45).

Parenchymal deposits within the liver classify the patient as *stage IV*; parenchymal disease within the spleen appears to have a similar prognostic implication.¹⁵⁰

Detection of peritoneal seedlings, especially en plaque tumor, is easier in the presence of ascites. However, CT can detect the calcified tumor implants containing psammoma bodies from serous cystadenocarcinoma of the ovary even in the absence of ascites.¹¹³ Conversely, densely calcified tumor implants from serous tumors may be mistaken for bowel containing oral contrast agent (Fig. 44-46). This is an important cause of understaging of ovarian cancer. CT can detect 50% of implants that are 5 mm or more in

Figure 44-46. Calcified omental cake. CT scan through the upper pelvis shows omental metastasis (O) that mimics partially opacified small bowel.

diameter.¹⁹ Detection of these and smaller peritoneal seedlings remains the province of surgery.

CT is also widely used to document tumor response during chemotherapy, to monitor persistent or residual disease after therapy, and to detect recurrent ovarian cancer.^{108, 143} Before chemotherapy is begun, it is customary to obtain a baseline CT study and important to recognize postoperative findings that may lead to diagnostic confusion and, indeed, may mimic residual tumor.¹³⁰ There may be marked thickening at the vaginal vault, and fluid collections may be seen here as well as in a variety of other pelvic locations. Hematoma of the round ligament may mimic cystic tumor on the pelvic sidewall. Ovarian vein thrombosis may also occur, with most cases occurring on the right side. Characteristic CT findings are of a tubular retroperitoneal mass along the course of the vein from the pelvis to the infrarenal vena cava.¹³⁶

In patients with recurrent ovarian cancer, CT findings may differ from findings at initial diagnosis. In the postoperative patient, the greater omentum is absent and thus omental cakes are rarely seen. Recurrent tumor may involve other peritoneal recesses and reflections, notably in the supracolic compartment around the spleen and stomach. Unopacified bowel loops may mimic recurrent peritoneal tumor. Meticulous CT technique with thinner sections and optimal bowel contrast opacification increases ability to detect recurrent disease.¹³¹ Adhesions from previous surgery, radiation therapy, or tumor may impair bowel opacification, and it can be useful to compare findings with previous CT studies to identify fixed loops of bowel.

Pelvic recurrence of ovarian cancer may be central, at the vaginal vault, associated with vaginal bleeding and discharge, or may be lateral, involving the pelvic sidewall with venous thrombosis or ureteric obstruction. Ascites may become loculated with displacement of adjacent organs; encysted lesser sac ascites may compress the stomach.¹⁴⁷ Lymphadenopathy may be pelvic or retroperitoneal or may even involve the mediastinum or neck. With serous tumors, this may be heavily calcified and may be mistaken for granulomatous lymphadenopathy.¹²⁵ Women with previous stage IV disease may experience relapse with pleural effusion.

Although CT cannot exclude small peritoneal deposits and thus cannot confirm disease remission at the conclusion of chemotherapy, it is rare nowadays for gynecologists to perform second-look laparotomies in order to restage patients. Women believed to be in remission are kept under surveillance with clinical and CA-125 assessment, and CT is reserved to clarify the site and extent of suspected recurrent disease. There is no evidence that routine CT surveillance is of value in follow-up in women in clinical and biochemical remission.

Most cases of malignant ovarian cancer are primary epithelial or metastatic neoplasms. Other malignancies include mixed müllerian tumors (carcinosarcomas with variable solid components), GCTs, sex cord stromal tumors (principally granulosa cell tumors), and neuroendocrine tumors. Although some of these pathologic conditions may be associated with larger solid elements, there are few distinguishing features in the primary lesion, although there are differences in the patterns of metastasis and relapse. Lung and parenchymal liver metastases are seen with some

of the more aggressive lesions, such as carcinosarcoma. Granulosa cell tumors may recur after many years with only localized and easily resectable masses. There is some evidence that CT may help predict long-term outcome with granulosa cell tumor; that is, patients with masses smaller than 9 cm and no CT evidence of lymphatic, peritoneal, or liver metastasis achieved complete remission.¹⁰¹

Epithelial ovarian tumors of borderline or low malignant potential represent up to 15% of ovarian neoplasms (see Fig. 44–35). Compared with invasive malignancy, these tumors are associated with a much better prognosis. Most mucinous lesions are stage I at diagnosis, but 45% of serous lesions are stage III, and these are bilateral in one third of cases.³⁴ There is no role for CT in follow-up of completely resected stage I borderline malignancy. CT is useful for more advanced disease, especially when chemotherapy is given and for providing an objective baseline examination in the assessment of progression. Disseminated mucinous borderline malignancy is a cause of pseudomyxoma peritonei.

The Treated Pelvis

Pelvic cancers are treated with radical intent by surgery and radiation therapy and with palliative intent by these modalities, either in combination or with chemotherapy. Radical surgery alters anatomic relationships within the pelvis. All of these treatment modalities result in early and late side effects. They may alter the patterns of disease spread when compared with a lack of treatment. The challenge is to recognize these treatment effects, and central to this is distinction between post-treatment scar and residual or recurrent cancer. Some of these issues are addressed in the discussions of specific organ, but two situations are commonly encountered in pelvic CT imaging: the *postresection* pelvis and the *postradiation* pelvis.

The Postresection Pelvis

The vagina is rarely the primary organ of CT examination. It is an extraperitoneal structure but may be exposed to intraperitoneal processes after hysterectomy for benign or malignant disease. The vaginal vault is a common site for recurrent tumor within the pelvic “sump.” After surgery, the vagina may become fixed to adjacent pelvic structures and may become secondarily involved by inflammatory or malignant conditions with development of enterovaginal or vesicovaginal fistulas. Fistulas are also recognized as late complications of radiation therapy. With a colovaginal or rectovaginal fistula, gas or feces may be present within the vaginal vault (Fig. 44–47). With a vesicovaginal fistula, contrast-opacified urine may be present within the vagina or may be soaked within the vaginal tampon. Delayed imaging with excreted contrast agent within the posterior bladder may be required to confirm the diagnosis (see Fig. 44–47).

Two cancer operations that result in gross distortion of the pelvic visceral anatomy are radical cystectomy and abdominoperineal resection of the rectum. After cystectomy, there is a pelvic void that becomes filled by pelvic small bowel and colon and, in women, by the gynecologic organs. An orthotopic ileal new bladder (conduit) is formed from loops of small bowel connecting the ureters with a urostomy on the lower abdominal wall, usually in the right iliac fossa. In men, the prostate gland and seminal vesicles are usually removed. The uterus, tubes, and ovaries may be retained and can assume unusual forms mimicking residual or recurrent tumor.

CT is useful in assessment of the postcystectomy patient.^{37, 93} In the early postoperative period, complications may include hematoma, urinoma, and abscess. Later the concern is for recurrent bladder cancer, and the pelvis is the most common site (see Fig. 44–22).³⁷ If there are pelvic adhesions, loops of small bowel may be fixed, poorly filled with oral contrast agent, and difficult to distinguish from

Figure 44–47. Radiation-induced fistulas. CT scan through the pelvis after radiation therapy for cancer of the cervix. A, Shown are fecal material (arrows) within a fistula between the rectum and the vagina (V) and a sliver of high-density contrast agent (arrow). B, Delayed excretory-phase image with contrast-filled urine in the bladder shows filling of the vagina with contrast of similar density to that in the rectum.

Figure 44-48. Postcystectomy appearances. CT scan through the pelvis in a patient with an ileal conduit mimicking unopacified small bowel (*arrows*). On adjacent sections, the conduit was able to be followed to the urostomy site (not shown).

recurrent disease without delayed or decubitus images. In one series,⁶¹ recognition of the range of normal appearances was important in assessment of the postcystectomy abdomen; the conduit was not identified as such in one third of patients. With spiral CT, the conduit is typically unopacified by urinary contrast material and has the appearance of fluid-filled or collapsed small bowel; however, the conduit can be traced from the skin to the ureters, and identification is improved by good oral contrast opacification of the other normal pelvic small-bowel loops (Fig. 44-48). Alternatively, the conduit may be distinguished from a fluid collection or bowel loop with the use of delayed images to allow filling with the excreted urinary contrast agent.⁶¹

After abdominoperineal resection of the rectum, the anterior pelvic organs fall back into the void.⁹² In men, the prostate gland and seminal vesicles fill the presacral space and the seminal vesicles may become distorted, mimicking residual or recurrent tumor. The trigone of the bladder may also become tethered into the void, resulting in an inverted, pear-shaped bladder. In women, the vagina, uterus, and adnexa fill the void. After surgery, the void may also be filled by hematoma and both sterile or infected fluid collections (Fig. 44-49).

These processes result in varying degrees of scar tissue and persistent mass lesions.⁷⁹ It is recommended that a baseline postoperative CT scan of the pelvis be obtained at 3 months against which future investigation of suspected recurrence can be compared.

The Postradiation Pelvis

Radiation therapy plays a major role in the radical and palliative treatment of pelvic cancers, historically for the prostate gland, bladder, and cervix but increasingly for the rectum. In addition to the desired treatment effects on the primary tumor, there are predictable effects on normal tissues. A variety of transient or progressive visceral com-

Figure 44-49. Postoperative hematoma. CT scan through the presacral space 3 months after abdominoperineal excision of the rectum. A thin-walled cyst (C) fills the excision site. Transperineal aspiration revealed altered blood.

plications occur and reflect the differing sensitivity of organs to radiation damage.⁷⁵ These include radiation enteritis and cystitis, stricture formation in the ureter, and, in severe cases, development of fistulas between pelvic organs, most commonly the bladder and vagina or bladder and bowel (see Fig. 44-47). The bowel is less tolerant than the urinary tract, and small-bowel loops are particularly susceptible to radiation effects if they are fixed within the pelvis by adhesions because the same loops are exposed to successive fractions of radiation. Late effects also include damage to bone with insufficiency fractures and radiation necrosis (Fig. 44-50).

In the first instance, symptomatic patients are usually investigated with cystoscopy, sigmoidoscopy, or contrast studies. Smooth, tapering strictures are typical of radiation damage but also occur with recurrent tumor, and CT has a role in excluding extramural masses and lymphadenopathy. After radiation therapy, the most frequent CT findings are thickening of the presacral space and perirectal tissues (Fig.

Figure 44-50. Insufficiency fractures. CT scan after radiation therapy for cancer of the cervix shows sclerotic and displaced bilateral pubic fractures (*arrows*).

Figure 44-51. Postradiation changes. CT scan through the rectum (R) in a man who had previously undergone radiation therapy for prostate cancer. There is perirectal stranding and thickening of the presacral space (arrows).

44–51). There may be atrophy and calcification of the prostate. Wall thickening, irregularity, and increased mucosal enhancement may be seen with acute injury to the bladder and bowel; more chronically, there is smooth thickening and matting of adjacent loops (Fig. 44–52).

The Post-treatment Mass

The differential diagnosis of a post-treatment mass includes postoperative change, postradiation scarring, and residual or recurrent tumor.¹³² In the specific example of assessment following abdominoperineal excision of the rectum, the diagnosis of presacral tumor recurrence may be confirmed when there is bony erosion or destruction of the sacrum, with new or enlarging masses and in the presence

Figure 44-52. Postradiation enteritis. CT scan through the pelvic small bowel, diffusely thickened in a woman who had undergone radiation therapy for cancer of the rectum. The uterus (U) is displaced backward into the surgical void (V).

of pelvic lymphadenopathy.¹⁰⁹ Masses larger than 4 cm that are globular and asymmetrical are probably due to recurrent tumor unless substantial postoperative bleeding or infection was present (see Fig. 44–49). This assessment emphasizes the importance of a baseline post-treatment study and highlights the limitations of CT, which relies on gross morphology and serial change.^{73, 76}

Alternative imaging techniques to CT for assessment of equivocal masses in the previously treated pelvis include MRI, particularly using signal intensity on T2-weighted images and dynamic gadolinium enhancement techniques, and nuclear medicine studies, including PET and immunoscintigraphy. Ultimately, image-guided biopsy may be required; in this context, however, only a positive diagnosis of tumor is of value.¹⁸ Endocavitary ultrasonography facilitates biopsy of masses deep in the central pelvis, but CT-guided biopsy may be required. This is most commonly undertaken from an anterolateral or trans-sciatic approach.

Fluid Collections

CT is widely used for the diagnosis and management of pelvic intraperitoneal and extraperitoneal abscesses, particularly in the postoperative setting. Although ultrasonography can identify most intraperitoneal fluid collections, diagnosis can be difficult in obese patients and in the postoperative setting with paralytic ileus caused by gas-filled bowel loops and when skin access is limited because of surgical dressings.

CT-guided abscess drainage may use a variety of approaches.^{17, 47} The preferred route for pelvic abscess drainage is an *anterolateral* approach through the abdominal wall; with this technique, the radiologist can avoid the pelvic sidewall vessels, bowel, and bladder (Fig. 44–53). When intervening bowel limits this approach, decubitus positioning may displace bowel to allow access. Otherwise, drainage can be achieved with the *trans-sciatic* approach through the greater sciatic foramen (Fig. 44–54).¹⁷ This technique is less popular. About 20% of patients experience pain during the procedure, and others subsequently find it extremely uncomfortable lying on the drainage tube.¹⁷ There is a risk of damage to the sacral plexus and the inferior gluteal vessels. For these reasons, alternative methods should be considered for drainage of deep pelvic fluid collections, particularly those in the pouch of Douglas. Increasingly, such collections are drained via the transrectal route or the transvaginal route using ultrasonographic guidance, although transrectal drainage with CT guidance has also been described.^{47, 163}

CT is used primarily for management of abscesses related to the gastrointestinal tract, particularly with acute diverticulitis (see Fig. 44–53) and appendicitis as a temporizing measure, with exacerbations of Crohn's disease (Fig. 44–55) and in the postoperative period. CT may also be used to facilitate drainage of large tubo-ovarian abscesses and, occasionally, in the management of complex pelvic urosepsis, but endocavitary ultrasonography is a preferred modality for drainage. Abscesses related to bowel disease may contain feces or thick pus, and large-bore drains are usually required to achieve effective drainage (see Fig. 44–53). Ultrasonography is of limited value in exclusion

Figure 44-53. Diverticular abscess. CT scan through a pelvic abscess. *A*, A fluid- and gas-filled cavity (*C*) lies anterior to the sacrum in a patient with known diverticular disease. *B*, After placement of a large-bore drain via a left anterolateral approach.

of infection within the retroperitoneum, such as psoas abscess (see Fig. 44-55), and in assessment of buttock and hip muscle compartments and the deep extraperitoneal pelvic and perineal spaces. CT is valuable for assessment of

these spaces, which may be affected by uncommon pelvic infections: gas-forming abscesses in diabetic and immuno-compromised patients; collections related to osteomyelitis and orthopedic surgery; and other complex soft tissue infections, including pyomyositis (Fig. 44-56).⁵⁷

After surgical procedures such as pelvic lymphadenectomy for cervical cancer and renal transplantation, a lymphocele may develop (Fig. 44-57). Typically, this type of fluid collection is discovered several weeks after surgery and must be distinguished from an infected collection or resolving hematoma. Lymphoceles contain fat globules and thus may have lower CT attenuation values than other collections, often less than 10 Hounsfield units (HU). A diagnostic needle aspiration may still be necessary; a lymphocele characteristically contains lymphocytes and fat globules. Lymphoceles often recur after aspiration, and thus percutaneous management requires either long-term catheter drainage or the use of sclerosing agents to obliterate the sac and its connections.^{162, 175}

Figure 44-54. Pelvic abscess. *A*, CT scan shows a pelvic fluid collection (*A*) anterolateral to the rectum (*R*). *B*, CT scan shows successful catheter drainage through the left sciatic notch.

Figure 44-55. Abscess secondary to Crohn's disease. CT scan shows a right psoas muscle abscess (*A*) containing fluid and gas adjacent to a thick-walled small-bowel loop (arrows).

Figure 44-56. Pyomyositis in a diabetic patient caused by *Streptococcus pyogenes* infection. CT scan shows extensive fluid collections surrounded by intravenous contrast enhancement involving the left obturator internus, piriformis, and gluteus medius muscles (arrows).

Lymphangiomas may have a similar CT appearance to that of lymphoceles but are more often multiloculated or composed of multiple adjacent locules. There may be calcifications. A variety of congenital and developmental anomalies may result in pelvic cystic collections, which may be incidentally discovered during CT examination. These include mesenteric and gastrointestinal tract duplication cysts and developmental cysts of the lower urogenital tract.

CT is a key modality for investigation of suspected pelvic hemorrhage. Trauma to the upper abdominal viscera may result in intraperitoneal hemorrhage, which collects in the pelvic sump. Hemorrhage may result in high-density fluid and in sedimentation with fluid-fluid levels (Fig. 44-58). Extraperitoneal hemorrhage is seen with pelvic bony or soft tissue injury. Other causes of pelvic and retroperitoneal bleeding include anticoagulant therapy (see Fig. 44-58), bleeding diatheses, and interventional procedures via the groin vessels. Hematomas within the psoas and rectus abdominis muscles are easily recognized in the acute phase in the appropriate clinical setting but may be more difficult

Figure 44-57. Lymphoceles. CT scan through bladder (B) shows bilateral large lymphoceles (L) surrounded by surgical clips from pelvic lymph node dissection.

Figure 44-58. Pelvic hematomas. CT scan through the pelvis shows high-density blood (B) within the left rectus abdominis muscle and layering out in the left pelvis in an extraperitoneal location. This elderly patient had taken an overdose of anticoagulant therapy.

to distinguish from abscess in the subacute and chronic phases.

Musculoskeletal Applications

MRI has replaced CT as the imaging technique of choice in the evaluation of pelvic soft tissue and bony tumors. It has superior soft tissue contrast and allows direct multiplanar imaging. A particular advantage is its ability to define the extent of bone marrow involvement, invasion of adjacent muscle compartments and neurovascular pedicles, and extension to joint surfaces.³⁰ When MRI is not available or when it is contraindicated, CT remains a useful imaging test for evaluating musculoskeletal tumors, and the volume acquisition of spiral CT allows MPRs, which may be valuable for planning reconstructive surgery.

Most patients with back pain or sciatica now undergo spinal MRI rather than CT. However, CT remains useful in assessing possible pelvic mass lesions compromising the lumbosacral plexus, particularly in patients with a history of pelvic cancer. MRI may be valuable after negative CT findings because it can detect a greater percentage of mass lesions involving the lumbosacral plexus.⁸ Improved soft tissue contrast, particularly with gadolinium enhancement, and direct coronal imaging along the path of nerve roots are particular advantages of MRI.

Pelvic Fractures

The key musculoskeletal application of CT within the pelvis is the assessment of complex bony injury. Indications for CT of the bony pelvis include (1) all pelvic ring disruptions with suspected or potential instability, (2) patients in whom stability cannot be properly assessed, and (3) inconclusive plain radiographs. CT is particularly

valuable for assessment of sacral and sacroiliac joint injury, acetabular fracture, and hip dislocation.

Familiarity with the clinically important fracture classifications is important to achieve optimal planning and interpretation of CT findings and in dialogue with clinical colleagues. The most widely used classification of major pelvic fractures, described by Young and Burgess, relates fracture appearances to the force of injury.¹⁸⁵ Injury to the pelvis may result from (1) lateral compression invariably with fracture of the pubic rami and usually with sacral injury, (2) anteroposterior compression with opening of the anterior pelvis, (3) vertical shear with vertically oriented anterior and posterior fractures typically resulting from a precipitous fall, or (4) from combinations of these forces. Letournel and Judet classified acetabular fractures on the basis of plain radiographs.⁹⁴ CT classification is divided into three types⁷⁰:

1. *Column* fractures split the acetabulum in a coronal plane into front and back halves.
2. *Transverse* fractures split the acetabulum in a sagittal plane into top (lateral) and bottom (medial) halves.
3. *Wall* fractures do not disrupt the load-bearing surface but may result in hip joint instability.

CT scans are superior to plain radiographs of the pelvis in the detection and classification of acetabular and sacral fractures.^{59, 100, 104, 116} In comparison with CT, radiography cannot reveal 57% of acetabular fractures, 34% of vertical shear injuries, and 29% of sacroiliac joint injuries. CT provides an axial display of both the anterior and the posterior columns of the hip and the articular surface of the acetabulum. CT is particularly valuable in showing small intra-articular fragments and in revealing fractures of the posterior acetabulum (Fig. 44–59). CT detects such fragments missed by radiography in up to 40% of cases.

Developments in spiral CT have further enhanced the surface of volumetric rendering techniques described for 3D imaging of acetabular and other pelvic fractures and are now available as an on-line facility.^{16, 41} Such images aid in planning the complex surgery for acetabular recon-

struction by mapping fracture fragment position and displacement and by assessing the integrity of the acetabular dome and quadrilateral surface.^{59, 100, 104} Sagittal and coronal reconstructions demonstrate the superior hip joint and acetabular dome with accurate definition of the acetabular surface.¹⁰⁴

There are potential pitfalls with surface-shaded reconstructions, particularly the inability to show small intra-articular fragments and undisplaced fractures, although these images dramatically illustrate overall fracture orientation and are appreciated by clinicians (Fig. 44–60). It is possible to electronically disarticulate the femoral head to allow inspection of the acetabulum. For optimal imaging of acetabular fractures, the use of overlapping slices using collimation of no more than 3 mm is advised. The imaging volume should extend up to the limit of any iliac fracture line and down into the ischium to show the entire obturator ring.

Sacral injuries occur in 4% to 74% of patients with pelvic fractures¹¹⁶ and are associated with neurologic and vascular injury and pelvic instability. CT is better than plain radiography in detecting sacral fractures and in demonstrating fracture pattern and extent.¹¹⁶ CT is useful in evaluating sacral injuries, including sacroiliac diastasis, fractures abutting the sacroiliac joint, vertical shear fractures, and comminuted fractures. Pelvic fractures associated with bladder injury are those of the pubis, sacrum, and iliac bone, including diastasis of the pubic symphysis and sacroiliac joint. Isolated acetabular injuries are rarely associated with bladder injury.¹¹⁸

Insufficiency (stress) fractures may affect the sacrum and pubis after radiation therapy (see Fig. 44–50) or may result from osteoporosis. Radiation-related fractures were seen in 5 (2%) of 183 women who underwent radical treatment for cervical cancer, with identified risk factors being prior connective tissue disorder, steroid use, and older age.¹⁰ Typically, these are vertical fractures of the sacral alae, parallel to the sacroiliac joints; however, they may be mistaken for metastatic disease. CT is an accurate means of displaying the fracture and excluding a destructive neoplastic process.²⁹

Figure 44–59. Pelvic fracture. CT scan shows a vertical fracture through the right posterior column of the acetabulum (arrow) and a displaced fracture of the anterior column (arrowhead). Only the anterior fracture was clearly shown by conventional radiography.

CT Pelvimetry

CT pelvimetry is performed when a vaginal delivery is contemplated with a breech presentation or if reduced pelvic dimensions are suspected, usually when difficulties have been encountered in a previous pregnancy. This technique is gradually replacing conventional radiographic pelvimetry because of the reduced radiation dose to the fetus.^{6, 39} A survey of departments in the United Kingdom showed a trend away from conventional radiography to CT but with emergence of low-dose digital fluoroscopy and MR pelvimetry as alternative techniques.¹⁵⁷

A variety of CT techniques have been described. The most extensive involve three views³⁹:

1. An anteroposterior scanogram to measure the transverse pelvic inlet diameter.
2. A lateral scanogram to determine the anteroposterior pelvic inlet diameter between pubis and sacrococcyx.
3. A single axial CT scan at the level of the foveae of the

Figure 44-60. Acetabular fracture. Comminuted vertical fracture through the right acetabular roof. A, Surface-shaded 3D CT scan viewed obliquely from above shows the fracture line (arrows). B, Axial section from the same examination volume shows fine detail of small fracture fragments (arrowheads) not appreciated on the 3D CT scan.

femoral heads to measure the distance between the ischial spines.

Increasingly, departments are using only a single view—the lateral scanogram—for assessment that achieves a 75% reduction in dose compared with conventional radiography.¹⁵⁷ There is a distinction to be made between pelvimetry in pregnant women, when a single view may be obtained, and in nonpregnant women, when three views may be obtained. The dose from three views increases fivefold over the single-view technique.⁶

There are a number of technical factors to consider, and various ploys are suggested to improve the accuracy of measurements.^{144, 177} It is important to position the pelvis near the center of the CT gantry for accurate CT measurements.^{39, 177} The ischial spines may lie up to 1 cm below the level of the foveae, leading to overestimation of the interspinous distance by about 1 cm.³ The distance between the spines is the narrowest point in the midpelvis and the site of most cases of obstructed labor.³ The lateral scanogram may better localize the level of the ischial spines for measurement with the axial CT section.

Lower Urinary Tract Trauma

Various bladder injuries may occur in patients with pelvic trauma, the most serious being intraperitoneal rupture, for which operative repair is required. Extraperitoneal rupture is four times more common and is usually managed nonoperatively with urinary catheter drainage. Distinguishing these two entities thus has major management significance. A few patients have combined space rupture. Bladder rupture occurs in about 10% of patients with pelvic fractures. Extraperitoneal rupture may be caused by bony fragments that directly contuse or rupture the bladder, with injury typically anterolaterally at the base. Intraperitoneal rupture usually results from a direct blow to the distended bladder, typically causing injury to the dome.

With each injury, there are predictable patterns of extravasation of contrast medium and urine into pelvic spaces. Extraperitoneal rupture involves the perivesical fat and obturator fossa (Fig. 44-61) but may extend to the anterior thigh and scrotum. Extravasation of opacified urine from the dome into the peritoneal spaces characterizes intraperitoneal rupture (Fig. 44-62).

Historically, conventional cystography has been the “gold standard” for evaluation of bladder trauma. Numerous studies have shown that CT cystography is as sensitive as cystography in detecting bladder injury.^{77, 96, 127} It is logical to use CT rather than conventional cystography in patients who are to undergo CT evaluation for other aspects of trauma. In such patients, CT affords a “one-stop” facil-

Figure 44-61. Extraperitoneal bladder rupture. CT cystogram via bladder catheter (B) shows extravasation of contrast agent into the left perivesical space (arrows). Note the bilateral pubic fractures (arrowheads).

Figure 44-62. Intraperitoneal bladder rupture. CT cystogram shows left-sided bladder wall rupture (arrow) and free intraperitoneal contrast agent (arrowheads). Note the presence of a right iliac blade fracture.

ity for differentiation of extraperitoneal from intraperitoneal fluid, identification and classification of associated pelvic fractures, and detection of other more life-threatening visceral injuries. The requirement for additional CT cystography is determined by a number of clinicoradiologic factors. In an unselected group of patients who underwent CT cystography for suspected bladder trauma, predictive features were pelvic fluid revealed on standard contrast-enhanced CT, gross hematuria, and pelvic fracture.¹¹⁸

With CT cystography, adequate bladder distention is required in order to detect contrast extravasation, and this is best achieved by retrograde instillation of 350 to 400 mL of 2% to 4% dilute contrast medium through an indwelling Foley catheter on the CT table after the standard CT study.⁹⁶ Alternatively, one may perform CT cystography by obtaining delayed CT images at 15 to 20 minutes through the bladder, relying on filling of the bladder with excreted urinary contrast material.⁷⁷ This method necessitates that the urinary catheter be clamped to achieve adequate bladder distention. There is greater variation in bladder filling and contrast opacification with this technique; consequently, the retrograde technique is preferred in most major trauma centers.

Vascular Applications

Internal Iliac Artery Aneurysm

Most internal iliac artery aneurysms occur in association with aortoiliac aneurysmal disease as a result of atherosclerosis. Isolated internal iliac artery aneurysms are rare and may present with a variety of clinical pictures as a result of their location and surrounding anatomic structures. They are potentially lethal lesions because their natural course is characterized by progressive expansion with relative lack of symptoms. Presentation may be misleading because of pressure effects on or erosion into adjacent structures, including the lower urinary tract, colon, pelvic vessels, and nerves or may be acute with rupture.^{35, 99} CT can elegantly demonstrate the aneurysm and its local effects and complications (Fig. 44-63).^{7, 105, 134} Some claim that it is more helpful than angiography in the evaluation of pelvic aneurysmal disease.¹¹⁹

Figure 44-63. Arteriovenous fistula from ruptured iliac aneurysm. CT shows a large left iliac artery aneurysm (A) with complex internal channels. There was rupture (arrowheads) into the iliac vein with early venous contrast opacification (arrow) on this arterial-phase study.

Lower Limb Swelling

Leg edema may be unilateral or bilateral, acute or chronic. It can be due to systemic illness (e.g., heart failure or hypoproteinemia), to a compressive process within the pelvis or retroperitoneum, or to a primary lymphatic abnormality. CT is particularly useful in demonstrating or excluding a pelvic sidewall mass as a cause of unilateral limb swelling once deep venous thrombosis has been excluded. It may reveal a retroperitoneal lesion compressing the inferior vena cava when there is bilateral edema. With longstanding edema, CT may help in differentiating primary lymphedema from chronic venous obstruction by demonstrating the honeycomb pattern of the subcutaneous compartment of the lower limbs in the former condition.^{56, 164}

Pelvic Lipomatosis

Pelvic lipomatosis is characterized by an abnormal deposition of adipose tissue within the pelvis surrounding the bladder, internal genital organs, and rectosigmoid colon. It is generally a benign condition with vague, nonspecific symptoms, but iliac vein obstruction and lower limb edema have been reported as a consequence.^{161, 183} Elevation and compression of the bladder, giving a pear-shaped deformity, and widening of the presacral space with straightening and elongation of the rectosigmoid colon are characteristic radiologic findings. The use of CT nicely demonstrates the presence of excessive pelvic fat, excludes a mass lesion as the cause of the deformity, and thus precludes the need for surgery.^{51, 86, 155}

Magnetic Resonance Imaging of the Pelvis

Eric K. Outwater

Since the first clinical reports of magnetic resonance imaging (MRI) of the pelvis, both the technical quality and range of applications of pelvic MRI have **increased**.^{29, 42, 129} High cost, slow spread of technical expertise in the community, and the absence of unequivocal clinical indications have delayed its widespread acceptance as an important imaging technique in the pelvis. Nonetheless, MRI has some definite advantages over other techniques of pelvic imaging, and further technical advances will serve to expand the range of applications.

Early investigators realized four potential advantages of MRI over conventional imaging techniques in the pelvis:

1. It offered direct multiplanar imaging, which is essential for clear depiction of organ anatomy and tissue planes in the pelvis.
2. Intrinsic soft tissue contrast of pelvic organs appeared to be high with MRI because of the multiple parameters of tissue proton relaxation that contribute to the MR signal.
3. The unique characteristics of moving protons on MR images promised unequivocal identification of vessels without necessarily using intravascular contrast material.
4. MRI appeared to be safe in pregnant patients.

These basic observations have provided the impetus for further research into potential clinical applications of MRI in the pelvis.

The great challenge in pelvic imaging is to find a cross-sectional technique that combines very high resolution with high tissue contrast and tissue specificity, sufficient safety to apply to pregnant patients, and low enough cost to apply in common clinical situations. No other technique currently fulfills all these criteria across a broad spectrum of applications.

Ultrasonography is the current imaging procedure of choice for most pelvic disorders. Its safety is established, and it provides sufficient depiction of normal and pathologic anatomy for routine assessment of many gynecologic and almost all obstetric disorders. Endoluminal probes and color Doppler imaging further expand its applications in the pelvis. Nonetheless, pelvic ultrasonography has serious limitations; for example, it is generally not suitable for one of the largest potential clinical applications—tumor staging. Resolution and tissue contrast are not sufficient for accurate staging of any genitourinary malignancies in males or females. In addition, the accuracy of diagnosis of adnexal masses is not sufficient to obviate surgical diagnosis in many cases. Taking these limitations into account,

cost-effectiveness of MRI has been suggested in several studies when ultrasound findings are equivocal, including for adnexal masses and scrotal imaging.^{323, 335} Incorporating MRI appears to save money in the evaluation of patients with cervical carcinoma and prostate carcinoma.^{138, 188, 189}

Computed tomography (CT) provides a more systematic examination of the pelvis than ultrasound, and it is better suited for defining bowel involvement in inflammatory and neoplastic disorders. CT is superior to ultrasound for depicting fat planes and adenopathy, which are important in staging malignancies. Aside from adipose tissue, however, soft tissue contrast is intrinsically poor on CT images of the pelvis. Zonal anatomy of the uterus or of the prostate is not demonstrated by CT, and depiction of perineal anatomy is limited. This poor tissue contrast, as well as the potential radiation risk in women of childbearing age, limits the general applicability of CT for the pelvis.

The risks of CT derive from the radiation dose and from the nephrotoxicity of intravenous (IV) contrast agents. Risks of radiation dose may be significant, particularly in younger patients. The probability of a radiation-induced cancer in a young adult undergoing CT of the abdomen and pelvis is about 1/2000 or greater.^{124, 300, 306, 307} The cost of this one-time radiation dose has been estimated at \$30 per millisievert, or \$300 per abdominal CT.^{306, 307} These considerations led one author to suggest that MRI in younger patients may be more cost-effective than CT on the basis of radiation risk alone.³⁰⁶ Costs associated with irradiation of unsuspected pregnancies have not been assessed. Further costs derive from risks associated with iodinated contrast agents, and cost-effectiveness favors MRI over CT for patients at risk for nephrotoxicity.¹⁹³

Important Imaging Techniques

The quality of MR images of the brain, spine, and musculoskeletal system exceeds that obtained in the chest, abdomen, and pelvis, primarily because of motion effects (respiratory, bowel peristalsis, and cardiac) and the lack of local receiver coils in the latter applications. Pelvic MR images are the least susceptible to motion effects but still suffer from suboptimal resolution because of the relatively large fields of view necessary to sustain a satisfactory signal-to-noise ratio (SNR). Two technical innovations—*multicoil (phased-array)* and *fast spin-echo (FSE)* sequences—can increase the SNR in pelvic images and shorten the acquisition time of long repetition time/echo time (TR/TE) pulse sequences. This time saving can be

used for higher-resolution matrices, acquisitions in multiple planes, or thinner sections, all of which are important in imaging the pelvis. In addition, improved methods of chemical shift imaging and vascular imaging allow added dimension to an overall examination of the pelvis.^{246, 348, 349}

Surface Coils

Two strategies have been developed for imaging the pelvis with surface coils: (1) *endoluminal* surface coils and (2) multiple arrays of *external* surface coils. Both of these take advantage of the higher SNR achievable with small-diameter receiver coils to achieve smaller fields of view, and hence higher resolution, than that obtainable with the whole-volume body coils in the bore of the magnet system. These techniques are more widely applicable to pelvic imaging than the surface coil arrangements that have always been available, such as a single-loop anterior surface coil for imaging the scrotum.

Endoluminal surface coils increase the SNR achievable with small (10- to 12-cm) fields of view. The sensitivity profile of these small-diameter coils falls off steeply as distance from the coil increases; thus, they are suited only for perirectal structures and organs such as the prostate,³²¹ anal canal,¹⁴⁷ and rectum.³¹⁹ Endoluminal surface coils can also image the cervix with high resolution, showing cervical carcinoma that spreads into the parametria.^{24, 228} These coils are less suited for imaging very bulky cervical tumors or other gynecologic neoplasms.

Multicoil (phased-array) arrangements have been designed for imaging the spine, abdomen, chest, and pelvis. Multiple separate receiver coils, preamplifiers, receiver channels, digitizers, and memory are used.^{116, 301} The signal

from each receiver is separately transformed into separate data sets, which are then reconstructed into a single composite image that uses an algorithm for the sum of the squares. Each coil is designed with a smaller effective diameter than would otherwise be used for a given volume of interest. The result is a composite image that can adequately include a larger area but with an SNR that is the same as or higher than that of a small-diameter coil.¹¹⁶ In this chapter, most images use a four-coil multicoil arrangement with two 5-inch coils anteriorly and two coils posteriorly. For imaging the true pelvis, coils can be arranged either craniocaudad or transversely.

Multicoil arrays share the disadvantages of all surface coils. The primary disadvantage is an intense signal near the coil, with a steep gradient of signal loss away from it.²¹⁸ This near-field effect renders the image very susceptible to ghosting artifacts that arise along the phase-encoding axis from the motion of structures (Fig. 45-1).²¹⁸ These ghost artifacts may be ameliorated by judicious choice of phase-encoding direction, anterior saturation bands,³⁴⁸ fat-suppression techniques, and physical restriction of the anterior pelvic wall. Multicoil arrays also impose additional burdens of increased memory demands and lengthened reconstruction times. Finally, the improvement in SNR of the multicoil over that of the body coil may be lost in particularly large patients, or in pregnant patients, because of the fall-off of sensitivity of the coils in the center of the imaging volume.³⁴⁸

Fast T2-Weighted Imaging

The development of FSE sequences was conceptually based on the RARE (rapid acquisition with relaxation en-

Figure 45-1. Comparison of conventional T2-weighted, fast spin-echo (FSE) images and single-shot FSE images for delineation of fetal anatomy. **A**, T2-weighted FSE image (TR = 2000 msec, TE_{eff} = 99 msec; two signal acquisitions) shows marked motion artifact related to fetal motion and maternal respiratory motion. Fetal anatomy is blurred and indistinct. **B**, Single-shot FSE image (TR = 16,000 msec, TE_{eff} = 96 msec, 0.5 half-Fourier acquisition) shows more discrete fetal anatomy with depiction of the cerebral lateral ventricles (arrowheads) and low-signal-intensity cerebral infarction (white arrow) in this patient with TORCH syndrome (toxoplasmosis, rubella, cytomegalovirus, herpes). TE_{eff}, effective echo time.

hancement) pulse sequence, first introduced by Hennig and colleagues.¹²⁰ Variants of these sequences—echo train spin echo, fast acquisition interleaved spin echo (FAISE), turbo spin echo (TSE), and gradient-recalled echo and spin echo (GRASE)—are grouped together under the term *fast spin echo* in this chapter.^{1, 224, 225, 283} These sequences employ multiple, closely spaced, refocusing pulses, called an *echo train*, for every 90-degree pulse.

Conventional spin-echo (SE) imaging uses a single refocusing pulse and acquires only one phase-encoded step per 90-degree pulse. A typical FSE sequence with an echo train length of 16 refocusing pulses reduces the acquisition time 16-fold. This time saving allows larger acquisition matrices or a greater number of acquisitions. The drawback of FSE is that fewer sections can be obtained in multislice acquisitions because a greater portion of TR is devoted to the echo train. However, interslice gaps can be avoided if two contiguous, interleaved acquisitions are performed.

Contrast in FSE can be manipulated by the ordering of phase-encoding trajectories in k-space. The time between the 90-degree pulse and the *n*th signal that is assigned to the lowest-order, phase-encoding step in k-space determines the effective echo time (TE_{eff}). The low-order, phase-encoded signals are those with the weakest phase-encoding gradients. These low-order, phase-encoding steps determine the relative contrast, or *T2-weighting*, of the sequence.^{69, 70, 198}

Three mechanisms assume the greatest importance in FSE tissue contrast in the pelvis: (1) modulation of J-coupling effects in lipids, (2) exaggeration of magnetization transfer effects, and (3) T2-dependent alteration of the point-spread function.^{69, 70}

In conventional SE sequences, lipid protons (*spins*) undergo phase dispersion as a result of the different chemical shifts produced by spin-spin couplings (J-coupling) of the hydrocarbon chain protons. This results in a relative loss of signal from lipids. In FSE images, this phase dispersion is reduced by frequent refocusing, resulting in preservation of the lipid signal on FSE images.

The clinical situation determines whether the high-signal-intensity fat on T2-weighted sequences becomes a help or a hindrance in interpretation of the images. As a rule, use of a TE_{eff} longer than would be used in conventional T2-weighted SE sequences is preferable (Table 45–1).²⁵⁶ This achieves more heavily T2-weighted images with correspondingly less fat signal intensity and relatively better conspicuity of edema and tumors, for example. For most

applications, it is preferable to have high signal intensity of fat on T2-weighted images. Suppression of fat results in an obscuring of the muscularis layer of the bladder, rectum, and vagina, making tumor invasion of these structures difficult to appreciate.

FSE also shows increased magnetization transfer effects when compared with conventional SE imaging.³⁴ This results from the multiple 180-degree refocusing pulses causing off-resonance saturation on the nonselected slice. In general, this results in lower signal intensity of tissues that contain large numbers of macromolecules, such as tumor tissue and smooth muscle, and accentuation of structures that have no magnetization transfer, such as fat or fluid.³⁵

Last, the effects of the point-spread function can work to alter edge definition of some objects in FSE images.^{69, 70} FSE phase-encoded steps are acquired during the evolution of T2 decay. Just as contrast is determined by the position of the low spatial frequencies in k-space, the fidelity of edges is determined by the placement of high spatial frequencies. This can lead to an *edge enhancement* if the high spatial frequencies are collected at the early echoes (heavily T2-weighted) or to *edge blurring* if the high spatial frequencies are collected at the late echoes (intermediate weighting).^{69, 70} Edge enhancement is more pronounced with longer-T2 structures, whereas structures with short T2 tend to be blurred.¹⁹⁸

The practical result of these effects in pelvis imaging is a slight additional sharpness and conspicuity of cysts and other fluid collections in FSE images acquired with long TE_{eff} (>100 msec). This effect may combine with magnetization transfer effects to highlight small ovarian cysts and other small fluid collections.²⁴⁶ This blurring of shorter T2 tissues is particularly pronounced with the single-shot FSE sequence, or HASTE (half-Fourier acquisition single-shot turbo spin echo). This effect limits the ability of the HASTE sequences to substitute for T2-weighted FSE images in the pelvis.³⁶

For the pelvis, the FSE sequence is particularly well suited to heavily T2-weighted images with a TE_{eff} of 80 to 140 msec and a TR of 3000 to 4000 msec.^{348, 349} A 256×256 acquisition matrix is used in conjunction with an 18- to 24-cm field of view, although finer matrices can be sustained in the pelvis (see Table 45–1). Respiratory gating and gradient moment nulling are usually unnecessary because respiratory motion artifacts are not usually a significant problem in pelvic MRI. Artifacts related to bowel

Table 45–1. MRI Protocol for the Female Pelvis*

Pulse Sequence	TR	TE	Matrix	Slice	SAT	NEX	FOV
†Cor FSE	4000	100	256 × 256	5 × 1	S, I	2	24 × 24

AxFatSat GRE	~400	min	256 × 128	5 × 1	Fat, S, I	1	20 × 20

*Technique: pelvic phased-array coil.

†Give glucagon 1.0 mg IM prior to study.

Ax, axial; Cor, coronal; Fat or FatSat, fat saturation; FOV, field of view; FSE, fast spin-echo; GRE, spoiled gradient-recalled echo; I, inferior; interl, interleaved; min, minimum; NEX, number of signal averages; S, superior; Sag, sagittal; SAT, saturation bands; T1-SE, T1-weighted spin echo; TE, echo time; TR, repetition time.

Figure 45-2. Use of glucagon to suppress motion artifact. Axial T2-weighted, fast spin-echo images (TR = 4000 msec, TE_{eff} = 12 msec) before (A) and after (B) intravenous administration of 0.1 mg glucagon. Glucagon improves the definition of the bowel wall and also results in fewer ghosting artifacts in the phase-encoding (right-to-left) axis. The septate high-signal-intensity left ovarian mass (arrow) with a central low-signal-intensity mural nodule proved to represent a cystadenofibroma. TE_{eff}, effective echo time.

motion can be suppressed with the use of glucagon (Fig. 45-2).

Single-Shot Fast Spin Echo

HASTE images were the first type of sequence to obtain high-quality T2-weighted SE-type images in a breath-holding period. HASTE sequences use a half-Fourier acquisition and a long echo-train FSE sequence to obtain all the data necessary to form k-space from a single acquisition, or a single shot.

Single-shot FSE sequences achieve relatively motion-free breath-hold images in the pelvis, with tissue contrast similar to that of more conventional T2-weighted FSE. For conventional pelvic imaging, they are advantageous in imaging the abdominal wall, mesenteric fat, and bowel without motion. The main disadvantage of these sequences is tissue blurring in the phase-encoding direction caused by alterations to the point-spread function (see FSE sequences earlier).

For certain specific applications, such as identification of fibroids, single-shot FSE sequences may be able to obtain a study in a shorter time.¹⁸⁰ Imaging of the bowel is better with single-shot FSE sequences for two reasons^{25, 232}:

1. Imaging time is short enough that peristalsis-related motion artifacts are reduced.
2. The presence of any high-signal-intensity luminal contents causes the mucosal surfaces to be imaged with high resolution.

MR images of the fetus have always been susceptible to motion-induced artifact from respiratory-induced movement of the uterus and gross movements of the fetus itself.^{211, 214} Motion of the fetus causes motion of the amniotic fluid around it, which generates a marked ghosting artifact and blurring. Traditionally, to scan for possible fetal abnormalities by conventional SE sequences or even FSE

sequence, it was often necessary to paralyze the fetus. FSE sequences may be suitable for imaging the placenta and uterus but often yield poor-quality images of the fetus itself because of motion-induced artifact.

Single-shot sequences dramatically improved the potential for obtaining good MR images of the fetus.^{7, 194} These images are acquired quickly (~1 second), before gross fetal motion has occurred. Although some images are degraded if fetal motion occurs during their acquisition, others are relatively free of motion artifact. Therefore, repeated acquisition of the sequences can be performed to obtain diagnostic images free of motion artifact. The blurring of soft tissue structures that HASTE sequences cause is of lesser importance in imaging the fetus because most structures are bordered by fluid and therefore result in sharp images.

Another approach to obtaining fetal scans is *echo-planar imaging*.¹⁵⁶ Like single-shot FSE, it can easily achieve images in less than a second; however, signal-to-noise considerations seem to favor single-shot FSE. Echo-planar imaging has been used to investigate aspects of lung and liver maturation.^{87, 88}

Fat-Selective Methods

Various forms of fat-suppression techniques have been developed and have widespread clinical utility in imaging the pelvis,^{169, 233} including:

- Chemical shift-sensitive methods, such as frequency-selective fat saturation¹⁶⁸
- Dixon technique^{80, 334, 363}
- Opposed-phase gradient-echo sequences³⁹⁸
- Short tau inversion recovery (STIR) technique

STIR suppresses all tissues with a T1 approximating that of fat. It is not chemical shift-specific and thus does not unequivocally identify fat-containing tissue.²³³

Frequency-selective fat saturation is the most widely available of the techniques performed at higher field strengths. It can be applied to T1-weighted or T2-weighted images to suppress signal from all aliphatic lipid protons in the volume. Fat and hemorrhage, both of which commonly show very high signal intensity on T1-weighted images, are distinguished by comparing fat-saturated T1-weighted images and T1-weighted images without fat saturation (Fig. 45–3). This technique is most often used in T1-weighted sequences after injection of IV contrast material to render enhancing structures more conspicuous relative to fat. In T2-weighted images, it permits reduced bandwidth technique to increase the SNR in the images and highlights pathologic conditions that may have T2 times approaching that of fat.²³⁶ Like the Dixon technique, frequency-selective saturation is very sensitive to magnetic field inhomogeneities.^{38, 414}

Opposed-phase images can be generated using SE (the *Dixon technique*) or *gradient-echo sequences*. Gradient-echo sequences do not use a refocusing radiofrequency pulse to rephase fat and water protons; therefore, the lipid signal cycles in and out of phase with the water signal during the TE period. Voxels containing lipids and water show higher signal intensity if the fat and water are in phase and additive than if they are out of phase and the fat and water signal cancel. At 1.5 Tesla, these resonances are in phase to yield maximal signal for voxels with lipid and fat at TEs that are a multiple of 4.4 msec and out of phase at TEs that are a multiple of 2.2 msec. Such opposed-phase images can be used to detect lipid in dermoids because the sebaceous lipid is generally mixed with water protons.⁴¹¹

Hybrid methods achieve maximal fat suppression by applying frequency-selective fat saturation to an opposed-phase image.^{38, 362} When frequency-selective fat saturation is used, some significant amount of residual signal remains in adipose tissue. This is because of the presence of olefinic lipids with resonances near that of water and because of

the steady-state effects of the fat-saturation pulse, which produce residual longitudinal magnetization of lipid protons. With the addition of opposed-phase imaging, these residual longitudinal magnetizations are out of phase at time TE, resulting in nearly complete loss of signal in adipose tissue (Fig. 45–4).⁵⁸ Hybrid techniques are the most reliable for fat suppression.³⁴⁰ They aid in the diagnosis of masses that are mostly lipid, such as dermoids (see Fig. 45–4) and are also useful in contrast-enhanced images (see Table 45–1).

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) can be used in the pelvis for an overall evaluation of veins or arteries. Several modalities are available:

- Gadolinium-enhanced, three-dimensional (3D) MRA
- Two-dimensional (2D) time-of-flight (TOF) MRA
- Phase-contrast MRA

These three techniques have been used to image pelvic arteries, although the first is generally preferred. Phase-contrast angiography is sometimes used in special circumstances in the abdomen but is not discussed here.

Time-of-Flight 2D Imaging

Of the various MRA sequences available, TOF-MRA gradient-echo imaging was used most widely before the development of faster imaging methods. TOF-MRA can provide gross evaluation of the major arteries of the pelvis to determine vessel or graft patency, vessel displacement or encasement by masses, or stenoses.¹¹ A sequence that can yield good results in the pelvis uses a minimum TE with gradient moment nulling, a TR of 33 to 45 msec, a 30-cm field of view, a 2.5-mm slice thickness contiguously acquired, and a 128 × 256 acquisition matrix. A flip angle

Figure 45–3. Endometriomas, chemical shift imaging. A, Axial spin-echo image (TR = 800 msec, TE_{eff} = 11 msec) demonstrates bilateral adnexal masses with signal intensity approaching that of fat. The left adnexal mass is partially septate. B, The same pulse sequence performed with frequency-selective presaturation of fat demonstrates that high signal intensity is not due to lipid. In addition, several small implants of endometriosis (arrows) are more easily seen. The subcutaneous fat signal is also suppressed. TE_{eff}, effective echo time.

Figure 45-4. Mature cystic teratoma, chemical shift imaging. A, Coronal image shows normal fetal anatomy (F) at 22 weeks of gestation. B, T2-weighted image shows the gravid uterus (F) and a complex right adnexal mass (arrow). The mass does not have the signal features of simple fluid. T1-weighted gradient-echo images with (C) and without (D) fat suppression show loss of signal of the lipid component (L) in the mass (arrow), establishing the diagnosis of a mature cystic teratoma. (From Ascher SM, Outwater EK, Reinhold C: Adnexa. In Semelka RC, Ascher SM, Reinhold C [eds]: *MRI of the Abdomen and Pelvis: A Text-Atlas*. New York, Wiley-Liss, 1997, pp 661-715.¹²)

of 60 degrees works well in most instances, although a lower flip angle may be used when prominent arterial pulsation artifact is present.^{281, 367}

TOF-MRA imaging generally works well for imaging the pelvic veins, whereas the pelvic arteries have provided a greater challenge.³⁵¹ This is partly because prominent arterial pulsations are normally present in the pelvic arteries, leading to marked differences in flow-related enhancement from phase-encoding step to phase-encoding step. The changes in flow-related enhancement lead to prominent ghosting artifacts and resultant loss of signal intensity in the pelvic arteries.

Additionally, the pelvic arteries are frequently tortuous and thus susceptible to in-plane flow saturation on TOF images.

Finally, the pelvic arteries are vulnerable to magnetic susceptibility artifact resulting from neighboring colon. Because the pelvic arteries are of crucial importance for the

imaging evaluation of patients with claudication or tissue loss, precise delineation of any stenoses is crucial. For these reasons, adequate imaging of the pelvic arteries awaited the development of fast imaging techniques with gadolinium enhancement.³⁵¹

Gadolinium-Enhanced 3D Imaging

In overcoming the problems associated with TOF-MRA, 3D MRA with gadolinium proved to be a major advance. With the short echo time of this 3D MRA, magnetic susceptibility artifacts are not as noticeable. The dramatically shortened T1 of blood provided by gadolinium eliminates the in-plane flow saturation that was frequently seen in tortuous arteries. Finally, because the 3D MRA technique relies on imaging blood by virtue of its shortened T1 and not flow-related enhancement per se, this technique is not susceptible to the alterations in flow-related enhancement

that led to the view-to-view errors and pulsations of artifacts of the 2D TOF technique.

Details of gadolinium-enhanced, 3D gradient-echo imaging are presented elsewhere.²⁸⁶ Briefly, this technique involves the use of a 3D gradient-echo acquisition to image a volume with thin sections amenable to 3D reconstruction and reformatting. This sort of sequence can be performed with more conventional gradient systems; however, the high performance gradients, with a higher gradient strength and slew rates, mean that the 3D sequence can be performed in a shorter time period. Acquisition of the 3D sequence in a shorter time means that timing the acquisition to the bolus is less problematic and the sequence can be performed with breath-holding to eliminate some sources of motion.

For imaging the pelvis, slab thickness and orientation must be chosen. This differs from the TOF-MRA technique, in which the pelvis is imaged in cross-section (axially) and final reconstructions are made in the anteroposterior projection. The coronal plane or slab is chosen to include the target vessels, and the section thickness determines the final resolution. The 3D gradient-echo sequence is obtained with minimum TE and TR. Because of the large number of phase-encoded steps involved in the acquisition, the minimum TR obtainable dramatically affects the total acquisition time. IV gadolinium is injected, and the plateau of arterial phase enhancement is timed to correspond to the center of k-space acquisition of the 3D gradient-echo scan. If the 3D sequence is a half-Fourier acquisition, the center of k-space may occur at the beginning of the acquisition rather than in the center. Saturation bands for suppression of venous in-flow are not possible, and selective imaging of the arterial systems depends on critical timing so that venous enhancement has not occurred (Fig. 45-5).

Several studies have shown greater accuracy with the

3D gadolinium-enhanced technique than with the 2D TOF technique.^{2, 85, 287, 350-352} Pitfalls in the 3D technique are related primarily to technical problems with the performance of the examination. Because gadolinium dramatically shortens the T1 of the blood, selective in-flow saturation of venous vessels is far less effective with the gadolinium-enhanced technique than with the TOF technique.

Gadolinium-enhanced 3D sequences have been used in a number of applications in the pelvis.^{99, 201} They provide more accurate identification of stenoses in the iliac arteries than conventional TOF sequences. Three-dimensional, gadolinium-enhanced MRA is particularly well suited for patients with complex arterial grafts in place (see Fig. 45-5). Imaging of femoral bypass grafts was particularly a problem with 2D TOF imaging because of the in-plane flow saturation. With 3D gadolinium-enhancement, the flow direction is irrelevant; therefore, flow in grafts running in any direction can be effectively imaged. Surgical clips may still cause artifactual stenosis with 3D gadolinium-enhanced sequences, but the problem is less profound than with 2D TOF imaging because the TE of the 3D sequence is much shorter.

Gadolinium-enhanced 3D sequences are useful in identifying stenosis and thrombosis affecting renal transplants, arteries, and veins.¹⁵⁵ Because of the short transient time of arterial blood through the kidneys, it is relatively simple to image both arteries and veins with this modality. These sequences can detect arterial lesions associated with impotence.³⁵⁶ The potential of gadolinium-enhanced 3D sequences in delineating arterial supply in other pelvic disorders per se has not been explored.

Magnetic Resonance Venography

MR venography using TOF sequences reliably demonstrates the common femoral veins, the external and internal

Figure 45-5. Infected femoral graft and venous thrombosis in a 73-year-old woman, shown by gadolinium-enhanced, 3D gradient-echo imaging. *A*, Projection reconstruction of a coronal slab from a gradient-echo sequence (TR = 13 msec, TE = 2.3 msec) shows a completely occluded left iliac arterial system. The right arterial system is severely diseased with multiple stenoses (arrows). A patent cross-graft femoral-to-popliteal graft is seen (arrowheads). *B*, Venous phase of the 3D technique shows focal enhancement around the graft (arrowheads), which proved to represent infection in the graft. Numerous collateral veins from bilateral iliac venous occlusions can be seen. (From Outwater EK: Ultrafast MR imaging of the pelvis. *Eur J Radiol* 29:233-244, 1999.²⁵⁵)

Figure 45-6. Diagnosis of thrombosis by MR venography. Reconstruction from axial 2D time-of-flight gradient-echo images (TR = 7.7 msec, TE = 45 msec, flip angle of 60 degrees, 120 slices of 2.5-mm thickness) shows filling defects in the left common femoral vein (arrow). The presence of thrombosis was confirmed on venography.

iliac veins, and the inferior vena cava (Fig. 45-6).³⁵⁵ MR venography is inferior to direct iliac or femoral injection contrast venography for demonstrating the iliac veins, but it is often superior to routine pedal injection for lower extremity venography. Venous occlusions due to thromboses or tumor encasement can be identified (see Fig. 45-6).^{11, 355, 367} Gadolinium enhancement may increase the conspicuity of thrombi.⁹⁵ The presence of an apparent flow defect on the maximum intensity projection images must be compared to the axial gradient-echo or SE images to verify the presence of thrombus (Fig. 45-7). Venous compression and magnetic field inhomogeneity artifacts due to metal commonly result in an appearance similar to that of thrombus.

MRI Anatomy of the Pelvis

Male Pelvic System

Anatomic details of the male genital system are best appreciated with the highest possible resolution, which requires the use of surface coils to support smaller fields of view. For the scrotum, this is easily accomplished with a circular loop coil placed directly over the scrotum.^{212, 295, 330} For the prostate, it is best achieved with a pelvic multicoil arrangement or the use of an endorectal coil. Body coil imaging with large fields does not permit the high resolution needed to identify important landmarks such as the prostatic capsule and the neurovascular bundles of the prostate.^{134, 273, 318, 369} T2-weighted images display the zonal anatomy of the prostate and the testicular adnexa to best advantage; acquisition in the axial and coronal or oblique coronal planes is usually the most desirable.^{134, 191, 273, 318, 369} T1-weighted images are important in assessment of the integrity of the periprostatic fat and neurovascular bundle and in identification of sites of hemorrhage.

Prostate Gland

The zonal anatomy of the prostate gland and its alteration, caused by *benign prostatic hyperplasia* (BPH), is somewhat complex. For imaging purposes, whether by ultrasound or MRI, the prostate gland usually displays three main regions: the central gland, the peripheral zone, and the anterior fibromuscular stroma (see Fig. 45-7).^{134, 197, 280, 320}

The *central gland* in older men is usually involved, to some degree, by hyperplastic changes and shows lower signal intensity than the surrounding peripheral gland.^{163, 274, 314} The central gland, as it appears on MR images, includes the anatomic designations of the central and transitional zones.^{318, 320} The central and transitional zones are histologically and anatomically distinct,^{15, 220} but the echogenicity on ultrasound and MR signal intensity characteristics are similar. In addition, the distinction between these becomes distorted and obscured by the development of hyperplasia.³²⁰

The *peripheral zone* shows higher signal intensity on T2-weighted images because of the presence of generally larger and more numerous glandular lumina than in the fibromuscular tissue of the central gland.³¹⁸ When the gland is affected by BPH, a thin, low-signal-intensity boundary usually appears between the central nodules and the peripheral gland.

The *anterior fibromuscular stroma* is a low-signal-intensity structure occupying the anterior edge of the prostate (Fig. 45-8).^{134, 273}

The apex of the prostate, approximately the inferior 1.5 cm, is composed primarily of peripheral zone and urethra unless considerable BPH is present. Coronal T2-weighted images show the apex best (see Fig. 45-7). The central zone of the prostate extends from the verumontanum to the base of the gland, becoming progressively wider superiorly so that at the base it occupies most of the transverse area of the prostate. The lower signal intensity of this tissue is similar to that of a prostate carcinoma, rendering the base of the gland a more difficult area in which to identify carcinomas.

The prostatic capsule is not a true capsule but a thin fibromuscular band that blends with the prostatic stroma and, to a lesser extent, the periprostatic tissues. This band is incomplete at the apex.^{15, 402} On T2-weighted images, the prostatic capsule appears as a thin, low-signal-intensity line at the margin of the prostate (see Fig. 45-7).^{266, 318, 320} This band tends to have a signal intensity similar to that of tumors, rendering direct assessment of its integrity difficult when tumors abut the capsule. Posteriorly, the capsule blends with the prerectal fascia of Denonvilliers.⁴⁰² Nerves and vessels lie in the adjacent pericapsular fat. These are particularly prominent anterior to the apex (the anterior periprostatic plexus) and posterolateral to the peripheral zone (the neurovascular bundles). The neurovascular bundles are important structures to assess for nerve-sparing prostatectomy.³⁶⁹ The venous plexus around the prostate shows high signal intensity on T2-weighted images (see Fig. 45-7).²⁷⁹

The seminal vesicles are easily identified on MR images as convoluted tubular structures coursing posterior and superior to the base of the prostate (Fig. 45-9). The seminal fluid within the lumina and glandular mucosa show high

Figure 45-7. MRI anatomy of the prostate. Cadaveric sections (A and E) and MR images (B and D) demonstrate some of the anatomic features in the male pelvis.

A, Transverse section at the midprostate shows the inner gland (I) and the outer gland (O) of the prostate. The neurovascular bundles (black arrows) and the ejaculatory ducts (black arrowhead) are demonstrated. The prostatic capsule appears as a low-signal-intensity rim (open arrows).

B, T1-weighted, spin-echo image shows little differentiation of central and peripheral gland. The neurovascular bundles are demonstrated laterally (arrows). The arrowhead indicates the ejaculatory duct.

C, T2-weighted, fast spin-echo image is much better for differentiating between the inner (I) and the outer (O) prostate gland. Ejaculatory ducts (arrowhead) and neurovascular bundles and prostatic capsule (open arrows) are shown.

D and E, Coronal T2-weighted (D) and cadaveric (E) images through the posterior prostate show the seminal vesicles and ejaculatory ducts (arrowheads), seminal vesicles and ampulla of the vas deferens (SV), the periprostatic venous plexus (black arrowheads), and the levator ani muscle (LAN).

Figure 45-8. Sagittal midline, T2-weighted, fast spin-echo, endorectal coil imaging of the prostate gland. The seminal vesicles (white arrow), ejaculatory ducts (black arrowheads), bladder neck and prostatic urethra (open arrows), membranous urethra (white arrowheads), anterior fibromuscular stroma (FMS) and peripheral zone (PZ), and bladder wall (black arrows) are shown. Small nodules of benign prostatic hypertrophy can be seen bulging the trigone of the bladder (curved arrow).

Figure 45-9. Anatomy of the seminal vesicles. Cadaveric sections through the seminal vesicles (A) and T1-weighted (B) and T2-weighted (C) endorectal coil images of the seminal vesicles show the slightly thick-walled vas deferens (arrows in A and C), the seminal vesicles (SV), and the periprostatic venous plexus (PV). The T1 shortening that occurs throughout the left seminal vesicle and the left vas deferens, indicating the presence of postbiopsy hemorrhage, does not pose diagnostic difficulty because the T2-weighted, fast spin-echo image does not show the low signal intensity that would indicate the presence of tumor invasion.

signal intensity on T2-weighted images. The walls show low signal intensity.^{266, 318, 320} The size of the seminal vesicles is highly variable. Because spread of tumor to the seminal vesicles occurs directly from the base of the gland or via the ejaculatory ducts,⁴⁰² it is important to image the inferior aspect of the seminal vesicles separately from the (low-signal-intensity) base of the gland with coronal or sagittal images. Medially, the vesicles terminate just posterolateral to the ampullae of the vas deferens, which demonstrate a thicker, low-signal-intensity wall (see Fig. 45-9).

The course of the vas deferens can be traced from the spermatic cord in the inguinal canal, laterally along the pelvic sidewall, and then medially to the base of the prostate gland. The distal few centimeters of each vas widens to form the ampulla, which contains the tortuous lumen and a thicker muscular wall (see Fig. 45-9). This thickening should not be confused with seminal vesicle invasion by prostatic carcinoma.

Scrotum

Scrotal MRI is usually performed to evaluate testicular abnormalities. The testis, like the peripheral zone of the prostate, demonstrates a fairly long T2 and, therefore, fairly high signal intensity on T2-weighted images.^{19, 212, 295, 330} The signal intensity is homogeneous, except for faint, low-signal-intensity septa sometimes seen radiating from the low-signal-intensity mediastinum testis (Fig. 45-10).^{212, 330}

The testis is invested in a thin, low-signal-intensity

capsule, which represents the tunica albuginea and the tunica vaginalis.¹⁹ The latter reflects over the bare area of the testis, thus serving to anchor the testis to the scrotal wall, and covers the interior of the scrotum as the parietal tunica vaginalis.¹⁹ The epididymis demonstrates inhomogeneous intermediate signal intensity on T2-weighted images (see Fig. 45-10).³³⁰ High-signal-intensity venous vessels of the pampiniform plexus surround the vas deferens in the spermatic cord and frequently obscure it.

Female Pelvic Anatomy

Female genital anatomy is best displayed on T2-weighted images. The sagittal plane is ideal for demonstrating the uterine zonal anatomy and vaginal anatomy and for showing the relationship of abnormalities of these organs to the bladder and rectum. Therefore, imaging in this plane and one other plane, usually axial, is important to adequately evaluate the female pelvis. T1-weighted images, offering information somewhat similar to that obtainable from CT scanning, show poor soft tissue contrast; however, these images are important for defining fat planes, adenopathy, and fat or hemorrhage in pathologic masses.

MRI provides striking depiction of the anatomy of the uterus, yielding information unavailable by other imaging techniques. The inner high-signal-intensity stripe, which represents the glandular tissue of the endometrium,^{192, 215} is sharply demarcated from the very-low-signal-intensity deeper myometrium (the "junctional zone") (Fig. 45-11).

Figure 45-10. Anatomy of the scrotum. A, Transverse T1-weighted image (TR = 500 msec, TE = 15 msec) shows the normal intermediate signal intensity of the testes (T). B, T2-weighted, fast spin-echo image (TR = 4000 msec, TE_{eff} = 115 msec) shows high signal of the testes. Radiating septa of the mediastinum testis (black arrowhead) are seen. Bilateral hydroceles separate the tunica albuginea covering the testis (white arrow) from that covering the internal surface of the scrotum. C, Coronal T2-weighted, fast spin-echo, surface coil image of the scrotum (TR = 4500 msec, TE_{eff} = 140 msec) shows normal high signal intensity of the testes (T) (arrows). The heads of the epididymides are seen with intermediate signal intensity. The pampiniform plexus (P) is demonstrated as tortuous venous vessels. Faint septa radiating from the mediastinum testis are seen in the right testis. TE_{eff}, effective echo time.

Figure 45-11. Uterine anatomy as shown by sagittal imaging. T2-weighted, multicoll image (TR = 4000, TE_{eff} = 126) demonstrates the uterus with a normal-appearing junctional zone (white arrowheads). An anterior indentation of the endometrium can be seen at the site of a prior cesarean section (white arrow). The urethral wall (open arrow) and the normal bladder wall (curved arrow) are demonstrated. A tampon lies within the vagina (V). TE_{eff}, effective echo time.

This represents a compact, more cellular smooth muscle zone with a lower water content than the outer myometrium.^{41, 216, 326} The bulk of the myometrium appears as intermediate-signal-intensity tissue with numerous high-signal-intensity small vessels running through it. To a variable degree, a thin, patchy subserosal low-signal-intensity layer may appear, also representing a smooth muscle zone similar to the junctional zone.^{192, 215, 326}

The endometrium increases in thickness during the follicular phase of the cycle.²¹⁷ In women taking oral contraceptives, no such increase occurs; the endometrium is, in fact, thinner than normal throughout the cycle.²¹⁷ In addition, signal intensity on T2-weighted images is increased in these women.²¹⁷ Blood products with variable signal intensity on T1-weighted and T2-weighted images may appear in the uterine cavity during the menses and after dilatation and curettage.^{13, 217} In postmenopausal women, the myometrium tends to lose signal and thus the contrast between the junctional zone and the outer myometrium decreases.

The cervix demonstrates a low-signal-intensity stroma that is continuous with the low signal intensity of the uterine corpus. This occupies a greater proportion of the cervical wall than the uterine body, with a correspondingly thinner outer myometrium.³²⁸ The cervical mucosa and submucosa can be distinguished from cervical canal glandular secretions.²¹⁵ Depending on the level, the cervix is bordered externally by the lumen of the vaginal fornices (posteriorly and laterally); by the vesicovaginal septum (anteriorly); by the parametrial tissues, including cardinal ligaments, uterosacral ligaments, and paracervical venous plexus (laterally); and by the peritoneum of the cul-de-sac (posteriorly) (Fig. 45-12). These adjacent structures serve as important routes of invasion by cervical carcinoma.

High-resolution, T2-weighted images depict the normal ovaries as having an intermediate-signal-intensity central stroma with numerous high-signal-intensity follicular cysts

Figure 45-12. Axial MRI evaluation of the cervix. T2-weighted, fast spin-echo image through the cervix and vaginal fornices (*white arrows*) shows the low-signal-intensity cervical myometrium. Several small nabothian cysts (*white arrowhead*) are also seen. The perivaginal and pericervical plexus veins appear as high-signal-intensity structures in the parametrium (*black arrows*).

and a low-signal-intensity cortex (Fig. 45-13).^{257, 265} On high-resolution, long-TR/TE FSE images, these cysts may appear more numerous than is encountered with conventional body-coil SE techniques because of the higher resolution and contrast provided by heavily T2-weighted FSE sequences.^{215, 348} This appearance should not be confused with polycystic ovarian disease, which shows innumerable cysts peripherally situated, with a fibrotic ovarian tunica (Fig. 45-14). The identification of ovarian follicular cysts by MRI is important in definitively identifying structures as ovaries. The presence of small follicular cysts splayed around an adnexal mass can help the radiologist to ascertain the ovarian origin of a mass (Fig. 45-15). Postmenopausal ovaries demonstrate fewer, smaller cysts or an absence of cysts (Fig. 45-16).^{257, 265}

Round ligaments are identified as low-signal-intensity structures coursing from the uterine cornua toward the inguinal canal. The peritoneal reflections of the broad ligament are not visualized except when bordered by ascites. The uterine arteries and veins within the broad ligaments, however, can be seen, and they serve as a landmark for the broad ligament (see Fig. 45-13). Normal fallopian tubes are usually not well depicted. Dilatation of the tubes by fluid or blood renders the tubes visible as serpentine, high-signal-intensity structures with a discrete low-signal-intensity muscularis.²⁶⁰

Bladder and Rectum

Four layers of the bladder wall are important for staging of bladder carcinoma: the mucosa, the lamina propria, and two muscular layers. Depending on the pulse sequence used, the degree of bladder distention, and any pathologic processes affecting the bladder, usually one or two of these layers can be seen on MR images.⁹⁰

On T2-weighted images, the hypointense muscularis of the wall can always be discerned; high-resolution studies may depict more than one muscular layer. The inner muscularis layer shows very low signal intensity on T2-weighted images and the outer muscular layer shows intermediate signal intensity because of its looser muscle structure.²⁴³ Inflamed submucosa or lamina propria may exhibit high signal intensity on T2-weighted images, similar to urine in the bladder.¹²²

Intermediate-weighted images may depict this abnormal layer as high signal intensity contrasting with low-signal-intensity urine.^{90, 91} Gadolinium-enhanced T1-weighted images can depict the mucosa as a thin, enhancing rim internal to the bladder wall.^{245, 364}

The layered structure of the rectal wall is best depicted by high-resolution imaging with an endorectal coil.^{147, 148} With this technique, the muscularis can be discerned and the mucosa and submucosa can be seen (Fig. 45-17).⁵⁷ High-resolution imaging of the rectal wall shows the low signal intensity of the mucosa and muscularis contrasted with the higher-signal-intensity submucosa on T2-weighted images.¹⁴⁸ No other technique can show the relationships of the rectum to important structures, such as the puborectalis and levator ani, with the multiplanar capability of MRI.³⁹³

Figure 45-13. Normal ovaries in a 33-year-old woman.

A, T1-weighted, spin-echo image (TR = 617 msec, TE = 16 msec) shows the ovaries (black arrows) poorly differentiated from adjacent adnexal structures. Signal voids in the pelvic side wall and broad ligament vessels (white arrowheads) can be seen. A faint hyperintense focus is in the right ovary (thin white arrow).

B, Axial T2-weighted, fast spin-echo image (TR = 3817 msec, TE_{eff} = 119 msec) shows the right and left ovaries (black arrows). Multiple follicles are seen in the right ovary and a cyst is seen in the left ovary (open arrow). A normal amount of cul-de-sac fluid is identified (black arrowheads). The small endometriosis focus (thin white arrow) shows low signal intensity. TE_{eff}, effective echo time.

C, Fat-saturated, gradient-echo image (TR = 300 msec, TE = 2.9 msec), as in A, shows poor differentiation of the ovaries from the surrounding adnexa. The high-signal-intensity focus in A retains its high signal intensity (arrow), establishing that it is not fat.

D, Gadolinium-enhanced, fat-saturated, gradient-echo image (TR = 300 msec, TE = 2.9 msec) shows enhancement of both ovaries (black arrows) to a lesser degree than the myometrium (M). The rim of the corpus luteum cyst on the left (open arrow) enhances.

Evaluation of the Male Pelvis

Benign Disorders

The value of MRI for benign disease affecting the male pelvis has not been well defined. Because of cost considerations, availability, and the nature of the information needed, ultrasonography generally has proved most useful for imaging of the scrotum and penis. Clinical evaluation alone serves to identify most infectious diseases affecting the male genitalia, such as prostatitis and epididymitis. Transrectal sonography can be used to adequately visualize various developmental abnormalities affecting the prostate and seminal vesicles. MRI does not replace contrast radiog-

raphy for evaluation of the urethra. Nonetheless, a number of applications for MRI have been described, and the technique may prove useful in selected cases when conventional evaluation is inadequate.

MRI may be of value as an alternative to CT in localizing undescended testes. A testis is undescended in about 3% of infants, but most of these descend by the age of 1 year. Cryptorchidism affects approximately 0.3% of the male population²⁰⁷ and may be bilateral in 25% of cases.²⁰⁷ Histologic changes in the malpositioned testis begin as early as 2 years of age and include tubular atrophy, fibrosis, small size, and a paucity of germ cells.²⁹⁹ The undescended testis is subject to a 10-fold to 40-fold increased risk

Figure 45-14. Polycystic ovarian syndrome in a 29-year-old woman. Axial T2-weighted, fast spin-echo image (TR = 4000 msec, TE_{eff} = 126 msec) shows a left ovary with innumerable high-signal-intensity peripheral cysts surrounded by a slightly thickened low-signal-intensity tunica (arrowheads). TE_{eff}, effective echo time.

of malignancy and an increased incidence of infertility; interestingly, there is an increased likelihood of both in the contralateral, normally descended testis as well.^{207, 299} Almost 50% of occluding malignancies in malpositioned testes occur in intra-abdominal testes.²⁰⁷

The standard therapy for cryptorchidism is surgical, either orchiopexy for cases discovered early or orchiectomy for patients older than 10 years of age.^{206, 207} Orchiopexy renders tumor surveillance easier and may decrease the incidence of malignancy.^{206, 207}

Most patients with cryptorchidism do not require radiologic evaluation because the testis can be palpated in the

Figure 45-15. Sertoli-Leydig cell tumor of the left ovary. T2-weighted, fast spin-echo image (TR = 4000 msec, TE_{eff} = 140 msec) through the cervix and left ovary depicts a solid mass arising within the left ovary (arrow), displacing and deforming the small follicular cysts (arrowheads). In this 17-year-old patient with virilization, the preoperative imaging diagnosis of ovarian stromal neoplasm was made. TE_{eff}, effective echo time.

Figure 45-16. Normal postmenopausal ovaries. Coronal T2-weighted, fast spin-echo image (TR = 4000, TE_{eff} = 140 msec) demonstrates small, low-signal-intensity ovaries. The ovarian vessels leading to the right ovary (arrows) and the presence of a tiny follicular cyst in each ovary (arrowheads) identify these structures as ovaries. (For reference, a 5-cm scale is on right side of image). TE_{eff}, effective echo time.

inguinal canal. In approximately 4% of these patients, the testis cannot be palpated.⁹³ In these cases, radiologic evaluation with CT or MRI may be beneficial in localizing the testis. CT has been useful in this regard,¹⁹⁰ but high sensitivity (94%) with MRI in a small series has also been reported.⁹³ The undescended testis may have lower signal intensity and may be smaller on T2-weighted images than the normal testis.⁹³ The importance of not confusing lymph nodes or the remnant pars intravaginalis gubernaculi has been stressed.³⁰³ MRI has also been used to identify polyorchidism on the basis of typical signal intensity and testicular morphology of the supernumerary testes.²⁰

In most cases of epididymo-orchitis, diagnostic imaging is not needed because the condition can be adequately evaluated on clinical grounds. Patients not responding to antimicrobial therapy or whose clinical history and examination findings are compatible with those of tumor may require imaging to exclude an abscess or intratesticular mass.³⁸³ The hallmark of intrascrotal infection is evidence of epididymal inflammation: increased size, increased signal on T2-weighted images, sympathetic hydrocele, and increased vascularity.^{18, 383} The increased vascularity may manifest itself as increased numbers of vessels and signal voids seen in vessels that usually display slower flow.^{18, 212, 383}

The testis often demonstrates evidence of orchitis as patchy areas of lower signal intensity, compared with the normally high signal intensity of testicular parenchyma (Fig. 45-18).^{18, 212, 383} The fluid usually evident in the scrotal sac may outline the bare area of the testis. Visualization of this structure helps to exclude testicular torsion, which may be in the clinical differential diagnosis of subacute scrotal pain.^{212, 383} If fluid within the hydrocele is other than simple fluid (i.e., has very long T1 and T2) the presence of hemorrhage or infection of the fluid is suggested. Gadolinium-enhanced images may be valuable in this regard to

Figure 45-17. Endorectal coil imaging of superficial rectal tumor. *A*, Axial T1-weighted, spin-echo image (TR = 500 msec, TE = 14 msec) shows posterolateral rectal wall thickening. *B*, Axial fast spin-echo image (TR = 3800, TE_{eff} = 133 msec) shows the mucosal tumor (*C*). *Black arrows* indicate the low-signal-intensity rectal muscularis propria. Normal mucosa (*white arrows*) appears as a thin intermediate-signal-intensity stripe. SV, seminal vesicles; TE_{eff}, effective echo time.

demonstrate necrotic or infarcted areas of the testis as nonenhancing areas.

Testicular torsion is related to abnormally diminutive attachments of the testis to the scrotal wall (the so-called bell-clapper deformity), resulting in the capacity of the testis to rotate and twist about the spermatic cord.³⁸³ Depending on the degree and duration of twist, this causes congestion and interstitial hemorrhage in the testis and progresses to hemorrhagic venous infarction due to venous occlusion.²⁹⁹ Arterial occlusion producing complete infarction occurs late and infrequently. Spermatic cord torsion typically occurs in the second and third decades. Testicular torsion is an acute surgical condition. If the diagnosis can be made within 24 hours, detorsion and orchiopexy may save the testis.

Dynamic testicular scintigraphy is the most common

means of assessing for testicular torsion and has generally high accuracy rates.¹²⁵ Color Doppler ultrasonography has also been used, with rates of 86% to 100% sensitivity and 100% specificity reported.^{47, 227} It is unlikely that MRI can improve on these results because currently there is no way to definitively demonstrate flow or the absence of flow in the pampiniform plexus and testicular artery by MRI.

MRI does reveal the parenchymal changes of torsion, however, showing hemorrhage and edema within the epididymis and testis. This produces lower than normal signal in the testicular parenchyma, often in a linear pattern radiating from the mediastinum.^{371, 383} The affected testicle tends to be smaller than normal. The epididymis enlarges and demonstrates heterogeneous low signal intensity, in a pattern similar to that seen with epididymitis. A key finding, if it can be identified, is the twisted portion of the spermatic cord producing a vortex of helical low-signal-intensity structures surrounded by high-signal-intensity edematous cord.³⁸³ In the absence of this torsion knot, it may be difficult to reliably distinguish torsion from inflammatory disorders of the testis. Torsion is typically not associated with the MRI evidence of increased vascularity seen in epididymo-orchitis.³⁸³

MRI with an endorectal coil has also been used in men with ejaculatory dysfunction to identify developmental abnormalities of the prostate and seminal vesicles.³²² Prostatic cysts along the course of the ejaculatory ducts (müllerian duct cysts),^{111, 372} seminal vesicle cysts associated with ipsilateral seminal vesicle and renal agenesis, seminal vesicle calculi, and some cases of chronic inflammatory disease of the prostate and seminal vesicles can be identified (Fig. 45-19).³²² Evidence of hemorrhage is frequently seen in the seminal vesicles (short T1 of fluid) in men with hemospemia.

Acute or chronic prostatitis is frequently seen histologically and may mimic the MRI findings of carcinoma in the peripheral zone.²⁷³ Prostatitis usually manifests as patchy, low-signal-intensity areas in the peripheral zone. Granulomatous prostatitis is indistinguishable from carcinoma by

Figure 45-18. Chronic epididymo-orchitis in a 30-year-old man with pulmonary and scrotal sarcoidosis. The hallmarks of chronic epididymo-orchitis are present, including the marked enlargement at the epididymides (*white arrows*), patchy low signal intensity in the testes (*black arrowheads*), and hydrocele (*curved arrow*).

Figure 45-19. MRI evaluation of ejaculatory dysfunction. *A*, Axial T1-weighted, spin-echo, endorectal coil image shows high-signal-intensity cystic mass in the left seminal vesicle (*asterisk*). Numerous periprostatic veins descend on the left (*arrowheads*), but the seminal vesicle on the left is atrophic. *B*, T2-weighted, fast spin-echo image shows the cystic nature of the mass and again shows absence of the seminal vesicle on the left. The right seminal vesicle is normal and better demonstrated on other images. These findings are typical of a wolffian duct cyst with seminal vesicle aplasia, which was confirmed pathologically.

MRI, with discrete low-signal-intensity nodular lesions (Fig. 45-20), or generalized low signal intensity in the peripheral zone. Prostatic abscesses can easily be identified with MRI, and the multiplanar display may aid in the planning of surgical drainage (see Fig. 45-25).

Malignancies of the Male Pelvis

Testicular Carcinoma

Testicular malignancies are a leading cause of cancer and account for 8.8% of deaths in 15- to 34-year-old males.¹¹⁸ Approximately 10% are associated with undescended testes.^{206, 207} Important genetic differences in incidence are seen; the rate in Africans and African Americans is low. Testicular neoplasms are frequently misdiagnosed

as epididymo-orchitis or other disorders on initial clinical examination.²⁶⁸ Therefore, a role may exist for imaging to distinguish testicular masses from extratesticular processes (Fig. 45-21). Treatment and, to a certain extent, MRI features are dependent on the cell type and extent.^{82, 126, 268}

Testicular neoplasms are broadly categorized into (1) germ cell tumors (~93%), (2) lymphomas (5%), and (3) sex cord-stromal tumors (2%). Sex cord-stromal cells are usually benign but capable of elaborating steroid hormones.

Germ cell tumors are further subdivided into *seminomatous tumors (seminomas)* and *nonseminomatous tumors*, an important distinction because of the different approaches to treatment of these two classes. In general, after orchiectomy and after the histologic type of tumor has been established, patients with seminomatous tumors receive radiation to the retroperitoneal lymph nodes, whereas pa-

Figure 45-20. Granulomatous prostatitis. *A*, Axial T1-weighted, spin-echo image (TR = 400 msec, TE = 12 msec) shows slightly hyperintense nodules within the prostate but a normal overall prostatic morphology. *B*, Axial fast spin-echo image (TR = 4000 msec, TE_{eff} = 140 msec) shows hypoechoic nodules within the peripheral zone (*arrows*). Pathologic examination of the cystoprostatectomy specimen in this patient, who had been treated with bacille Calmette-Guérin (BCG) therapy for a bladder carcinoma, showed only granulomatous prostatitis. The appearance of the low-signal-intensity nodules in the peripheral zone, however, is compatible with carcinoma. TE_{eff}, effective echo time.

Figure 45-21. MRI differentiation of a palpable, left-sided testicular mass in a 24-year-old man. *A*, An ultrasound examination had demonstrated a left testicular mass (M) that showed diffuse moderate echogenicity and was thought to be a solid lesion. Increased through-transmission, however, can be noted. *B*, T1-weighted, spin-echo image (TR = 500 msec, TE = 15 msec), shows a well-circumscribed mass (M) of low signal intensity. *C*, T2-weighted, fast spin-echo image (TR = 4000 msec, TE_{eff} = 115 msec), shows the mass (M) to have very high signal intensity. The appearance of the mass in *B* and *C* is consistent with that of a cyst, and pathologic examination showed an intratesticular left-sided epidermoid cyst. A small right-sided hydrocele can be seen in *C*. TE_{eff}, effective echo time.

tients with nonseminomatous tumors usually undergo retroperitoneal lymphadenectomy and chemotherapy.^{82, 126, 268} Approximately 30% of germ cell tumors appear to be of one cell type when combined criteria of histology and tumor markers are used.²⁹⁹

Seminomas are the most common type of germ cell tumor. The peak age of incidence is in the fourth and fifth decades, about one decade later than that of the nonseminomatous tumors. Pathologically, these tumors appear as solid, large masses without hemorrhage or necrosis, and they usually do not violate the tunica albuginea. On MR images, they appear as lobulated, more or less homogeneous intratesticular masses, and show predominantly intermediate signal on T2-weighted images, which contrasts with the high signal intensity of the remaining testicular tissue.¹⁵⁷ They are often large enough to replace the testicle entirely. Small associated hydroceles are common. Unlike the situation with epididymo-orchitis, the testicular adnexa, particularly the epididymis, appear normal when the testicular tumors are confined by the tunica albuginea (Fig. 45-22). Of course, more advanced tumors extend into the epididymis and enlarge it.

Nonseminomatous tumors include embryonal cell carcinomas, yolk sac tumors, teratomas, and choriocarcinomas, although most contain mixed elements. These tumors tend to be locally advanced, with a higher likelihood of metastases than is the case with seminomas. MRI demonstrates

Figure 45-22. Clinically palpable abnormality of the testis in a 31-year-old man. Sagittal T2-weighted, fast spin-echo image (TR = 4500 msec, TE_{eff} = 140 msec) shows a low-signal-intensity mass in the superior pole of the testis without involvement of the overlying epididymis. The mass, which is confined by the tunica albuginea, proved to represent a Sertoli-Leydig cell tumor. TE_{eff}, effective echo time.

considerably more heterogeneity, compared with seminomas, and areas of high and low signal intensity on T2-weighted images.¹⁵⁷ A thin, low-signal-intensity capsule is a common finding.¹⁵⁷

MRI, like ultrasonography, cannot distinguish benign from malignant intratesticular masses, except for simple lesions such as cysts (see Fig. 45-21) and hematomas.^{212, 295, 330, 371} Therefore, orchiectomy is indicated for any solitary intratesticular mass. MRI may be more accurate than ultrasound in establishing the presence of diffuse infiltrating neoplasm involving the testis on the basis of diffusely decreased signal intensity.³⁷¹

The role of pre-orchietomy ultrasound or MRI for local staging of testicular neoplasms has not been defined. Initial studies have indicated poor accuracy of both ultrasound and MRI for this purpose.³⁷¹ Most attention has been focused on cross-sectional imaging of the retroperitoneum to determine lymph node metastases. Although MRI may be equally sensitive in detecting enlarged lymph nodes,⁸³ it cannot distinguish carcinomatous lymphadenopathy from benign lymphadenopathy. CT and MRI have accuracy rates of 75% to 80% for staging the retroperitoneum in patients with testicular carcinoma.^{118, 277} Because lymphadenectomy can certainly improve these rates and is often believed to be therapeutic as well as diagnostic, it is preferred for initial management of low-stage disease.^{82, 118, 277}

Prostate Carcinoma

Prostate carcinoma is the most common carcinoma discovered in men and the third leading cause of cancer mortality, with an estimated 39,000 deaths per year.¹⁸⁶ Studies of autopsies and prostatectomy specimens have demonstrated that clinically inapparent prostate carcinomas have a very high general prevalence in older men—an incidence of up to 80% in men older than 80 years of age.^{324, 337} Most of these incidental carcinomas are low-volume, well-differentiated carcinomas with a good prognosis without treatment.^{100, 154, 220, 324, 337, 357} Approximately 90% of these tumors remain undetected during the lifetime of the individual.¹⁰⁰ Relatively recent innovations, such as prostate-specific antigen (PSA) screening and ultrasound-guided biopsy, however, may considerably increase the number of carcinomas that are discovered.⁵⁶ There is evidence today that prostate carcinoma may be discovered at an earlier stage than previously.²⁷²

Clinicopathologic studies have revealed the major prognostic determinants of localized prostate carcinomas. Stage of disease, specifically the presence of capsular penetration and seminal vesicle invasion, was one of the first variables to be identified.⁵¹ Capsular penetration and seminal vesicle invasion correlate with the presence of lymph node metastases, and with a poorer prognosis, and are generally considered a relative contraindication to prostatectomy.

The critical prognostic importance of cancer volume is also being realized. The incidence of lymph node metastases strongly correlates with the grade and volume of the tumor.^{220, 395} These important determinants of cancer volume, grade, and local stage have provided part of the impetus for developing an imaging technique that can accurately depict the extent and volume of prostate carcinoma.²⁴¹ MRI demonstrates a higher accuracy for measure-

ment of prostate volume than transrectal ultrasound.²⁹⁰ This is especially important for calculating PSA corrections to distinguish patients with elevated PSA levels caused by BPH from those caused by carcinoma.^{56, 250}

Approximately 5% to 10% of carcinomas arise in the central zone of the prostate. The remainder arise within the transitional zone of the gland, from which most benign prostatic hyperplasia nodules also arise, or from the peripheral zone. Most clinically significant prostate carcinomas arise in the peripheral zone. These distinctions are important because cancers largely confined to the central gland or within areas of BPH are generally not apparent with either ultrasonography or MRI.

Fortunately, most transitional zone tumors are low-volume, low-grade lesions that uncommonly extend outside the prostate gland or to the seminal vesicles.^{105, 106, 220, 403} Incidental small foci of tumor discovered at transurethral resection of the prostate (TURP) may require no treatment; however, many stage A2 lesions may represent high-volume disease and may benefit from prostatectomy.^{105, 337, 403, 421} Clinical staging of these lesions is often inaccurate,⁴²¹ and although tumor grade and PSA level may help stratify them, an accurate staging modality would be of benefit in managing the disease.^{241, 337}

Prostate tumors spread by invasion through the prostatic capsule, by invasion of the seminal vesicles, by invasion of the bladder base, and by lymphatic spread to regional lymph nodes. Perineural invasion is a well-described feature of prostatic carcinoma, and although the presence of intraprostatic perineural spread is not itself a significant finding, the nerves serve as conduits to capsular transgression.^{91, 147} Neural branches penetrate the capsule from the neurovascular bundle at the posterolateral edge of the prostate gland, at the superolateral margin, and at the apex.²²⁰ These are the more common sites of capsular penetration (Fig. 45-23).

At the apex, such capsular penetration commonly results in positive surgical margins because of the difficulty of obtaining adequate margins around the prostate deep within the surgical field.^{220, 221} In prostatectomy specimens (i.e., clinically stage B carcinomas), capsular penetration is often very shallow (<3 mm).²²¹ This fact highlights the need for high-resolution imaging for detection of capsular penetration.

Staging lymphadenectomy is generally performed before prostatectomy. The relative inaccuracy of lymphangiography and CT for determining spread to lymph nodes has led most urologists to sample nodes prior to prostatectomy. Spread typically occurs first to the hypogastric, obturator lymph nodes and, less commonly, to the external iliac chains.²¹⁹ Evaluation of these nodes with CT or MRI can obviate lymphadenectomy if the suspected nodes can be shown to contain metastasis by needle aspiration. The complication rate associated with lymphadenectomy is about 20% to 30%.²¹⁹

The choice of treatment of prostatic carcinoma depends on many variables, including the clinical stage and grade of tumor, age of the patient, and concerns of the particular patient.⁴⁰³ Options for treating early-stage disease range from no treatment to hormonal manipulation, radiation, and prostatectomy.^{154, 347, 403} Stage A2 and stage B lesions show approximately equal survival rates with prostatectomy and

Figure 45-23. Invasion of the neurovascular bundle by prostate carcinoma. Axial T2-weighted fast spin-echo image (TR = 5000 msec, TE_{eff} = 140 msec) shows normal high-signal intensity to the right peripheral zone (white arrows). A low-signal-intensity mass in the left posterolateral peripheral zone invades the left neurovascular bundle (black arrow) and invades through the capsule on the left side. The central gland is markedly enlarged and has the typical appearance of benign prostatic hyperplasia. TE_{eff}, effective echo time.

radiation therapy.^{100, 403} However, rates of potency preservation above the approximately 50% level achievable with radiation therapy can be attained only with nerve-sparing prostatectomy or, possibly, with radioisotope implants.^{100, 357}

The high levels of contrast between some carcinomas and the surrounding peripheral zone on MR images led to early enthusiasm for use of the technique in staging prostate cancer (Fig. 45-24; see Fig. 45-23).^{127, 133, 274} Subsequent studies demonstrated fairly poor overall accuracy for MRI staging of prostate carcinoma, at least with the standard body receiver coil. Specifically, poor accuracy for staging results from an inability to assess capsular penetration and seminal vesicle invasion and frequently from an inability to even identify the tumor nodule.

Prostate tumors may not be correctly identified on MR images for several reasons:

1. Tumors may occur in the central gland, where contrast with the surrounding tissue is nil.
2. Tumors may infiltrate into the stroma of the peripheral zone without replacing glandular spaces so that no contrast in MRI signal intensity is apparent even though the tumor may be widespread.
3. Tumors may be imbedded in or surrounded by hemorrhage, prostatitis, or stromal fibrosis and thus may be obscured.

Figure 45-24. Peripheral zone prostate carcinoma. A, Transrectal ultrasonography shows a left-sided area of hypoechogenicity in the peripheral zone, the site of suspected carcinoma in this patient. Biopsy findings of the left side were negative, whereas biopsy results of the right peripheral zone were positive. B, Axial T1-weighted, endorectal coil image shows hemorrhage throughout the peripheral zone of the prostate. Hemorrhage does not enter a small focus in the right posterior peripheral zone (arrow). C, T2-weighted, fast spin-echo image shows low signal intensity in the right peripheral zone (arrow), indicating the site of the tumor. Signal intensity is similar to that in the central gland. D, Whole-mount section of the prostate shows the right-sided cancer (arrow) in the peripheral zone.

4. Other processes such as infection or fibrosis may mimic carcinoma by replacing glandular spaces with tissue.^{55, 258}

The hallmark of prostate carcinoma on T2-weighted images is a relatively low-signal-intensity nodule in the high-signal-intensity peripheral zone (see Figs. 45-23 and 45-24). The signal intensity of the tissue within the prostate—whether fibrosis, tumor, or BPH—generally correlates with the number and size of glandular spaces.^{288, 313} Specifically, the presence of larger and more numerous glandular fluid-filled spaces results in higher signal intensity on T2-weighted images.²⁸⁸ The conspicuity of tumor nodules depends, to a large degree, on the replacement of the normal glandular spaces of the peripheral zone with more cellular tumor.

Normal variation in the amount of stromal tissue in the peripheral zone may result in areas of fibromuscular stroma that reflect low signal intensity within the peripheral zone.^{54, 288} In some cases, prostate carcinoma may exhibit high signal intensity on T2-weighted images,^{54, 253} rendering differentiation from the peripheral zone difficult. Variants of prostate carcinoma as well as other prostate neoplasms may show high signal intensity on T2-weighted images.^{23, 79, 253}

Because MRI is usually performed for staging purposes after biopsy, hemorrhage within the gland is a common finding (see Fig. 45-24). High signal intensity on T1-weighted images persists for weeks or months after biopsy. It is difficult to locate tumor within an area of hemorrhage with certainty because hemorrhage may result in some low signal intensity on T2-weighted images.

Capsular penetration is most easily recognized on MR images when gross tumor is visualized outside the confines of the capsule (see Fig. 45-23). Unfortunately, tumor penetration of the capsule often occurs on a smaller scale, frequently apparent only on microscopic examination.²⁵⁸ An indirect sign, such as bulging of the capsule or slight

irregularity, may be of value in some cases (Figs. 45-25 and 45-26).^{315, 369} Particular attention must be paid to the prostate apex and base, not only because these are frequent sites of capsular penetration but also because they may be particularly difficult areas to examine by MRI. Coronal images are important in evaluating tumor extension at the apex and base. In patients with prostate cancer, MRI has shown overall poor accuracy (55% to 69%) in identifying capsular penetration using the body coil.^{298, 316} Higher accuracies (58% to 79%) are reported for the endorectal coil.^{142, 271, 302, 308, 417} Select groups of patients with intermediate Gleason grades and PSA levels may show higher accuracies.⁷³

Seminal vesicle invasion has been categorized into three types on the basis of pathologic studies of prostatectomy specimens⁴⁰²:

Type I invasion, the most common (40% of patients), involves extension along the ejaculatory ducts superiorly into the medial aspect of the seminal vesicles or ampullae of the vas deferens.

Type II invasion (30%) involves direct growth superiorly from the base of the prostate into the periprostatic tissue and then into the seminal vesicles.

Type III invasion (30%) involves foci of tumor within the seminal vesicles without evident connection to tumor in the prostate. These foci may represent metastases.

Capsular penetration is common with types I and II.⁴⁰²

The most reliable MRI sign of seminal vesicle invasion is gross replacement of the fluid-filled lumina by low-signal-intensity tumor (Fig. 45-27). As when identifying a tumor nodule in the peripheral zone, one must be aware that areas showing low signal intensity on T2-weighted images and high signal intensity on T1-weighted images usually represent hemorrhage.²³¹ Localized amyloid deposi-

Figure 45-25. Capsular penetration by prostate carcinoma. *A*, T2-weighted, fast spin-echo, endorectal coil image shows the normal high-signal-intensity peripheral zone (PZ) laterally and the low-signal-intensity tumor (T) on both sides of the gland. The irregularity of the capsule can be noted posteriorly (arrowheads). *B*, Whole-mount histologic sections show the darker-staining tumor (T) on both sides of the gland. Multifocal sites of capsular penetration occurred posteriorly. (From Outwater EK, Petersen RO, Siegelman ES, et al: Prostate carcinoma: Assessment of diagnostic criteria for capsular penetration on endorectal coil MR images. *Radiology* 193: 333-339, 1994.²⁵⁸)

Figure 45-26. Capsular penetration by prostate carcinoma. Axial T1-weighted, fast spin-echo image (A), T2-weighted, fast spin-echo image (B), and whole-mount section (C) of the prostate show a left-sided peripheral zone tumor (white arrows on B and C). The subtle capsular bulging (arrowheads) evident in B corresponds to capsular penetration seen in C. Signal voids in A and B result from calcifications within the central gland, which also shows nodular changes indicative of benign prostatic hyperplasia. In A, the image shows evidence of high-signal-intensity methemoglobin in both the right and left sides of the peripheral zone, although it tends to be excluded from the tumor. The neurovascular bundle on the left (black arrow) is intact. The urethra (curved arrows in B and C) and the utricle can be visualized.

Figure 45-27. Early seminal vesicle invasion. A, Axial T2-weighted, fast spin-echo image of the seminal vesicles shows normal seminal vesicles laterally (black arrows). Centrally, however, the abnormal low-signal-intensity tumor tissue (open arrow) lying along the left seminal vesicle and surrounding the vas deferens represents early tumor invasion of the seminal vesicle. B, On the gadolinium-enhanced, T1-weighted image, the abnormal low-signal-intensity area enhances (open arrow), proving that it is solid tissue. The enhancement of the walls of the seminal vesicles is normal.

Figure 45-28. Seminal vesicle invasion not apparent on MRI. *A*, Axial T2-weighted, fast spin-echo, endorectal coil image through the seminal vesicles in a patient with known prostate carcinoma shows normal-appearing seminal vesicles bilaterally. *B*, Gadolinium-enhanced, T1-weighted, spin-echo image through the seminal vesicles shows normal enhancement of the seminal vesicle walls. *C*, At surgery, diffuse tumor infiltration of the walls of both seminal vesicles was discovered (arrows). This image demonstrates the difficulty of detecting seminal vesicle invasion that does not fill the lumens of the seminal vesicles.

tion in the seminal vesicles, an uncommon but not rare occurrence, results in diffuse low signal intensity throughout the seminal vesicles.¹⁶⁴ Carcinoma often invades the seminal vesicles by invading through the walls, without replacement of the lumen with tumor. This form of spread is difficult to recognize on MR images (Fig. 45-28).

In most reports, the accuracy of MRI for staging prostate carcinoma has not been high. Endorectal coil imaging offers high-resolution imaging of the prostate; it is similar to intrarectal endosonography but offers better intraprostatic tissue contrast. Unfortunately, initial reports of high accuracy obtained with endorectal coil imaging were not supported by later studies.^{66, 142, 266, 271, 302, 308, 318, 417} Staging of prostate cancer by endorectal coil imaging, however, does appear to be more accurate than clinical staging and therefore may be the preferred mode. Furthermore, some studies have shown a cost savings if MRI is used to stage this disease and to help determine whether the patient should undergo prostatectomy or radiation therapy.^{188, 189} More recent research into the use of spectroscopy to identify the prostatic tumor has shown promise.^{183, 312, 419} Endorectal coils have also been used to identify tumor in the surgical bed after prostatectomy (Fig. 45-29).

Bladder and Rectum

Bladder Carcinoma

Bladder carcinoma is a very common tumor, the fourth most common tumor in men, and its incidence is rising.

Figure 45-29. Endorectal coil evaluation of a patient after prostatectomy. Sagittal midline, T2-weighted, fast spin-echo image (TR = 4000 msec, TE_{eff} = 140 msec) shows the bladder wall as a low-signal-intensity structure. The wide bladder neck down to the membranous urethra represents the appearance after prostatectomy. In this patient with a rising prostate-specific antigen level, a large nodule was found at the anastomotic site (arrow). Its appearance suggested recurrent tumor; at surgery, however, the diagnosis was recurrent benign prostatic hyperplasia. TE_{eff}, effective echo time.

Urothelial tumors demonstrate varying natural histories, depending on whether they are superficial or invasive. More than 70% of bladder cancer presents initially as a superficial (stage T1 or less) lesion.²⁸⁹ Approximately 80% of these remain confined to the mucosa or submucosa through most of their natural history.^{289, 293} Tumors that have invaded the muscle of the bladder wall at presentation, however, carry a worse prognosis, with a much higher incidence of pelvic lymph node metastases and a high rate of recurrence after resection.^{122, 289, 353}

The treatment of bladder tumors depends on whether the lesion is superficial or invasive (Table 45-2). Superficial tumors are candidates for intravesical therapy: transurethral resection of the bladder (TURB), cautery, photodynamic therapy and intravesical chemotherapy, or bacille Calmette-Guérin therapy.^{289, 353} Muscle-invasive tumors are generally treated with cystectomy, radiation therapy, or both.

For an imaging method to be useful as a staging tool, it must be able to distinguish T1 from T2 invasion.^{289, 329} Staging by TURB is inaccurate, resulting in understaging in approximately 30% of patients.^{122, 293, 329} Bimanual exam-

ination with the patient under anesthesia improves the accuracy of clinical staging, and some advocate this method to the exclusion of imaging for determining tumor stage.^{109, 122, 353} The depth of muscle invasion is less important because differences are not reflected in different survival rates.³²⁹ It is very important, however, to determine the spread of tumor into adjacent organs; this information may obviate the need for cystectomy.

On T1-weighted images, little or no contrast is evident between bladder tumors and the bladder wall (Fig. 45-30).^{77, 91, 177} T1-weighted images do provide, however, sharp delineation of the external bladder wall and the surrounding perivesical fat. On T2-weighted images, the bladder muscularis is better demonstrated, and tumors show intermediate to high signal intensity (Fig. 45-31). Depending on the TE and TR used, contrast between tumor and urine may be poor.^{77, 91, 177} In addition, differentiation between tumor and perivesical fat may be suboptimal on T2-weighted images (see Fig. 45-30).¹⁷⁷ Thus, the use of both T1-weighted and T2-weighted images, in multiple planes, is preferable for judging the extent of bladder tumors.^{77, 91, 177}

Because of the inadequacy of either T1-weighted or T2-

Figure 45-30. Superficial bladder carcinoma. A, Axial T1-weighted, spin-echo image (TR = 600 msec, TE = 18 msec) shows no evidence of spread of tumor into the perivesicular fat. The tumor itself as well as the bladder wall is poorly seen, however, because of the poor contrast between the urine and the tumor or the bladder wall. B, The T2-weighted, spin-echo image (TR = 2500 msec, TE = 80 msec) better demonstrates the tumor (arrow). Low-signal-intensity bladder muscularis (arrowheads) is seen underneath the polypoid tumor, indicating the superficial tumor. C, After administration of gadolinium, the axial T1-weighted spin-echo image shows the gadolinium within the urinary bladder outlining the tumor (arrow). The bladder wall enhances slightly and forms a continuous band (arrowheads) underneath the tumor, again verifying the superficial extent of the tumor.

Table 45-2. Local Staging of Bladder Cancer

TNM System	Modified Jewett	Pathologic Findings
TIS	CIS	Carcinoma in situ
Ta	O	Papillary tumor, noninvasive
T1	A	Invasion into lamina propria
T2	B1	Invasion into superficial muscle layer
T3a	B2	Invasion into deep muscle layer
T3b	C	Invasion into perivesical fat
T4a	D1	Invasion into prostate, uterus, vagina
T4b	D	Invasion into pelvic or abdominal wall

TNM, tumor-node-metastasis.

weighted images alone, gadolinium-enhanced imaging has been advocated for the evaluation of bladder tumors (see Fig. 45-30). Bladder tumors show enhancement similar to that shown by bladder mucosa/submucosa, which becomes visible as a thin, hyperintense lining of the bladder on contrast-enhanced, T1-weighted images.^{244, 364} A number of investigators have claimed that the additional contrast between muscularis and tumor evident on gadolinium-enhanced, T1-weighted images facilitates staging.^{245, 364, 366}

MRI has achieved overall staging accuracy of the primary tumor in 60% to 85% of patients.^{5, 50, 245, 366} The accuracies for distinguishing tumors that have penetrated the bladder wall (T3b) from those that have not (T3a or less) range from 73% to 100% (Table 45-3). In various reports, MRI has been found to be equivalent^{146, 294} or superior^{5, 364, 366} to CT. In one report, it is suggested that MRI is superior to transurethral ultrasound as well.³⁶⁴

Rectal Carcinoma

Surgery is the major component of therapy for rectal carcinoma, and pathologic staging is the standard. The prognosis is closely tied to pathologic stage. Accurate preoperative staging of rectal carcinoma is increasingly important because the approach to treating these tumors is evolving. The surgical approach is determined, to some extent, by preoperative estimation of the stage but, more important, by the anatomic level of the rectal mass. The use of preoperative radiation therapy has increased the need, at least on a research level, for assessment of the extent of these tumors and their response to radiation. Sphincter-sparing operations, instead of either abdominoperineal resections for low rectal lesions or local resections for superficial lesions, requires more accurate determination of depth of invasion of the carcinoma.

Figure 45-31. Bladder muscularis invasion. Fast spin-echo, multicore image (TR = 5000 msec, TE_{eff} = 120 msec) reveals a low-signal-intensity tumor occupying most of the left posterolateral wall of the bladder. The tumor effaces the low-signal-intensity muscularis (arrows), indicating deep invasion. TE_{eff}, effective echo time.

Locoregional recurrence is a much more significant problem in rectal carcinoma than in colon carcinoma.⁷⁸ Reported incidences of local recurrence after attempts at cure range from 10% to 40%.^{78, 204, 238} The risk of recurrence depends partly on the tumor level; the incidence of recurrence almost doubles in distal rectal tumors compared to the rate in higher rectal tumors.²⁰⁴

On T1-weighted images, rectal carcinoma appears as an intermediate-signal-intensity mass; its signal intensity is similar to that of the rectal wall (Fig. 45-32).⁴⁸ An intrarectal contrast agent, either insufflated air or a short-T1 liquid, aids in identifying the intraluminal tumor,⁷⁴ but it is not clear whether this is helpful for gauging transmural extent of the tumor. T1-weighted images provide excellent definition of the perirectal fat surrounding the rectal wall. With high resolution, fine stranding in the perirectal fat, radiating from the tumor, is discerned. This can occur in tumors confined by the wall and should not be interpreted as evidence of tumor spread.

On T2-weighted images, tumors have a variable appearance, reflecting their different histologic components.⁴⁸ Most tumors show intermediate signal intensity (see Fig. 45-32), but high-signal-intensity areas due to mucinous

Table 45-3. Accuracy of MRI for Staging Extravesicle Extension of Bladder Carcinoma

Figure 45-32. Pelvic and endorectal coil imaging of rectal carcinoma. *A*, T1-weighted, spin-echo multicore image shows hemicircumferential thickening of the rectal wall (arrows). *B*, T2-weighted, fast spin-echo image again demonstrates intermediate-signal-intensity thickening (arrows) compatible with tumor. The muscularis, however, is not well identified. *C*, T1-weighted, spin-echo, endorectal coil image shows the tumor in the right and left lateral walls of the rectum (arrows). *D*, T2-weighted, spin-echo image shows the intermediate-signal-intensity tumor (arrows) and invasion of the muscularis underlying the tumor (arrowheads).

areas and low-signal-intensity areas due to desmoplastic reaction are common. Complete disruption of the very-low-signal-intensity rectal muscularis propria is the key finding and indicates early transmural penetration (see Fig. 45-32).^{57, 148} Gadolinium-enhanced, T1-weighted images, preferably obtained with fat saturation, may also be useful. The muscularis enhances very little, providing some contrast between the enhancing tumor and muscularis (Fig. 45-33).

Staging of rectal carcinoma by imaging methods is a complex issue that involves comparative assessment of imaging modalities for detection of hepatic metastases, lymphadenopathy, and depth of mural tumor invasion. Of the three modalities used for staging rectal carcinoma (transrectal ultrasound, CT, and MRI), only CT and MRI can provide a comprehensive evaluation of these areas. In a few published studies, MRI has achieved sensitivities of

75% to 100% and specificities of 66% to 100% for detection of transmural extension.^{48, 74, 109}

As with staging of most malignancies by imaging, the lack of sensitivity and specificity for the detection of metastases to lymph nodes is a serious impediment to obtaining higher overall accuracy rates for staging rectal carcinoma.^{72, 123} If special pathologic techniques are used to examine all lymph nodes (regardless of size) in the surgical specimen, very high rates of metastases to lymph nodes 1 to 3 mm in diameter are discovered.¹²³ In one study, 78% of all nodal metastases from rectal carcinoma occurred in nodes less than or equal to 5 mm in diameter.¹²³ This insight shows that determining the presence of nodal metastases on the basis of lymph node size is difficult at best.

Endorectal coil imaging achieves higher staging accuracy compared with body-coil studies. Accuracies of 79%

Figure 45-33. Endorectal coil imaging of a rectal carcinoma. *A*, T1-weighted, spin-echo image shows thickening of the rectal wall caused by tumor (arrow), as well as intact perirectal fat (arrowheads). No evidence of tumor invasion into the prostate (P) can be seen. *B*, T2-weighted fast spin-echo images delineate the muscularis propria (arrowheads) underlying the tumor (arrow). The low-signal-intensity muscularis on the T2-weighted, fast spin-echo image is intact underneath the polypoid tumor, indicating that the muscularis at this level is not invaded. *C*, Gadolinium-enhanced T1-weighted image shows intact muscularis (arrowheads) and enhanced tumor (arrow). Pathologic examination showed that the tumor was confined to the muscularis. P, prostate.

to 81% in diagnosis of transmural penetration of the muscularis are reported.^{171, 226, 252} This imaging modality has been found to be as accurate as endoluminal ultrasound.^{161, 171, 226, 368} Use of the endorectal coil is technically difficult, however, because placement is difficult or impossible with bulky or stenotic lesions, small lesions may be difficult to find, and long lesions may not be covered adequately with the coil. Furthermore, an additional study is required to assess the abdomen and pelvis for metastases.

Evaluation of the Female Pelvis

Because ultrasonography is usually the first modality used to image the female pelvis, MRI is restricted primarily for two indications^{61, 112, 136, 232, 234, 375}:

1. Diagnosis of a uterine or an adnexal abnormality not adequately characterized by ultrasonography.
2. Staging of gynecologic malignancies.

As a result of cost and safety concerns, MRI has a small role in routine evaluation of pelvic complaints, in most obstetric disorders, or in the detection of malignancies.

Benign Conditions

Several studies have shown that MRI can be useful in identifying pelvic abnormalities that are poorly characterized or misdiagnosed on ultrasonography.^{14, 136, 232, 296, 373, 400} Disorders that can be reliably identified by MRI include congenital uterine disorders, leiomyomas, adenomyosis, mature cystic teratomas, and, in some cases, endometriomas. The noninvasiveness of the technique is particularly important in pregnant patients. Accurate diagnosis of these masses requires attention to MRI technique, familiarity with diagnostic criteria, and good clinical judgment.

Uterus

Congenital Anomalies

The accuracy of MRI in classifying congenital deformities of the uterus is very high—75% to 100%.^{53, 229, 269} Pellerito and colleagues²⁶⁹ have reported that the accuracy of MRI exceeds that of hysterosalpingography and transvaginal ultrasonography, although the combination of these two probably correctly identifies the majority of uterine

anomalies.^{292, 415} Unicornuate uteri are identified by the presence of a nonbifurcating endometrium within the horn in contiguity with the cervix. A rudimentary horn, if present, may contain endometrium, leading to hematometra (blood accumulation in the uterus). Didelphis anomaly is easily recognized by the presence of two unicornuate uteri and two cervixes.

One of the more common distinctions to be made is between septate and bicornuate uteri. These two entities are treated differently; septations can be removed via hysteroscopy, whereas bicornuate uteri are repaired via laparotomy and metroplasty. Attempts to perform a septoplasty on what is actually a bicornuate uterus may lead to uterine perforation. Intervening tissue between the two cornua of bicornuate and septate uteri may resemble myometrium or fibrous tissue on T2-weighted images.^{229, 269} A more useful finding is the external shape of the uterine fundus, which is notched in bicornuate uteri but typically convex or flat in septate uteri (Fig. 45–34).²⁶⁹

MRI can also be used to image uterine abnormalities associated with diethylstilbestrol exposure.^{131, 389} Abnormalities include uterine hypoplasia, T-shaped uterus, constrictions of the endometrium, hydrosalpinges, and a shortened cervix.^{131, 389}

Leiomyomas

Leiomyomas (fibroids) of the uterus are the most common gynecologic masses, but relatively few become symptomatic. Fibroids show various signal intensities on T2-weighted MR images, from homogeneously hypointense to heterogeneously hyperintense. Most leiomyomas, however, display a characteristic MRI appearance, either peduncu-

lated or intramural, and are not confused with other uterine tumors.^{136, 141, 375, 400} MRI is more sensitive and specific for the diagnosis of leiomyoma than an ultrasound study or a hysterosalpingogram.⁸⁶

Leiomyomas show predominantly low signal intensity on long TR/TE images (Fig. 45–35).^{141, 203, 382, 400} They appear well defined and sharply margined from surrounding myometrium. MRI can be used to differentiate pedunculated fibroids from other adnexal masses and submucosal fibroids from endometrial lesions on the basis of this typical signal intensity and morphology (Fig. 45–36). Thin, hyperintense rims,²³⁷ as well as internal signal heterogeneity caused by hyaline or myxoid degeneration,^{136, 141, 382, 400} are sometimes seen, but these changes are usually not extensive enough to mimic a malignant adnexal neoplasm (Fig. 45–37). Only ovarian fibromas and thecomas commonly have signal intensity characteristics that match those of fibroids.

Leiomyomas may show intermediate signal intensity on T2-weighted images, similar to or slightly higher than the signal intensity of the normal outer myometrium. These changes are usually caused by the increased cellularity of the tumor.^{141, 412} Increased cellularity indicates a separate histologic type of leiomyoma, reflecting those that are rapidly growing and more responsive to hormonal therapy than typical leiomyomas. The gadolinium-enhancement characteristics of fibroids are variable, but cellular lesions are usually hypervascular.

Adenomyosis

Adenomyosis, first described in 1860 by Rokitansky, is characterized by the presence of endometrial glands and

Figure 45–34. Septate uterus. *A*, Hysterosalpingogram in a 43-year-old patient with infertility. Bilateral tubal patency and uterine cornua with an angle of divergence of less than 90 degrees are seen. The appearance is consistent with bicornuate or septate uterus. *B*, T2-weighted fast spin-echo image in the axial plane (TR = 6200 msec, TE_{eff} = 102 msec) shows the divergent uterine cornua with a morphology similar to that seen in the hysterosalpingogram. The external surface of the uterine fundus is normal (arrows). Thus, a bicornuate uterus is not present, and this uterus has a shallow uterine septum. Arrowhead indicates the uterine cervix. TE_{eff}, effective echo time.

Figure 45-35. Pedunculated leiomyoma. *A*, Axial T2-weighted, fast spin-echo image through the uterine fundus shows a large, well-circumscribed, low-signal-intensity mass (L) anterior to the uterine fundus (U). The low signal intensity of this mass suggests leiomyoma. Vessels arising from the myometrium can be seen supplying the mass (white arrows), confirming its myometrial origin. *B*, Dynamic gadolinium enhancement of a pedunculated leiomyoma shows a rapid enhancement of the leiomyoma (L) via vessels crossing from the myometrium (arrows). The enhancement of the myometrium is similar to that of the leiomyoma, and the enhancement of the endometrium is less.

stroma deep within the myometrium.¹⁶ Whorled hypertrophy of the myometrial smooth muscle occurs around the glands and results in low signal intensity of the lesion on MR images (Fig. 45-38). High-signal-intensity foci appearing within the nodules on T2-weighted images represent the glandular epithelium (see Fig. 45-47).^{203, 378} These are occasionally hemorrhagic.^{16, 378}

The prevalence of adenomyosis is high in the female population (~19% to 31% of women). Although adenomyosis is not usually symptomatic,¹⁶ it is sometimes associ-

ated with menorrhagia and dysmenorrhea. The overall uterine size is enlarged in 60% to 80% of patients.^{16, 382}

Endometrial Polyps

Benign abnormalities, most commonly polyps, greatly outnumber cancers in patients screened by transvaginal ultrasound for a thickened endometrium.^{187, 249, 338} Endometrial polyps, among the most common pathologic lesions of the uterine corpus,³⁴² are often found in patients taking tamoxifen.³¹⁷ These benign nodular protrusions of the endometrial surface consist of a stroma, composed of focally or diffusely dense fibrous or smooth muscle tissue, and irregularly distributed endometrial glands that frequently show cystic glandular hyperplasia.^{299, 317, 342}

MRI features do not accurately distinguish endometrial polyps from cancer. On T2-weighted MR images, the fibrous core of the polyps appears as a central area of low signal intensity (Fig. 45-39); cysts within the polyp may appear as discrete structures or as peripheral areas of high signal intensity.

Uterine Adnexa

Ovarian Cysts

The morphology of functional ovarian cysts is as expected from the ultrasound appearance. Follicular cysts show a thin, smooth wall on MR images, and the cyst contents generally demonstrate the signal intensity of simple fluid (i.e., low signal intensity on T1-weighted images and very high signal intensity on T2-weighted images).

Corpus luteum cysts exhibit a thicker wall, which represents the luteinized lining (Fig. 45-40). This wall can demonstrate intense enhancement with gadolinium. MRI commonly reveals evidence of hemorrhage within corpus

Figure 45-36. Submucosal leiomyoma in a patient with menorrhagia. Axial T2-weighted, fast spin-echo image (TR = 3500 msec, TE_{eff} = 80 msec) demonstrates a submucosal leiomyoma protruding into the endometrium (arrow). Incidentally noted are plexiform neurofibromas along the sciatic nerve in this patient with neurofibromatosis. TE_{eff}, effective echo time.

Figure 45-37. Myoma with myxoid degeneration. *A*, T2-weighted, fast spin-echo image shows a rounded mass (arrowheads) in the interior myometrium. Some low-signal-intensity components as well as patchy areas of very high signal intensity can be seen in this mass. *B*, Histologic section from an area of higher signal intensity shows abundant myxoid tissue (M) within the areas of whorled smooth muscle. (From Murase E, Siegelman ES, Outwater EK, et al: Uterine leiomyomas: Histopathologic features, MR imaging findings, differential diagnosis, and treatment. *Radiographics* 19:1179–1197, 1999.)

luteum cysts, with lower-signal-intensity blood or clot layering dependently in the cyst and shortened T1 and T2 of the cyst contents relative to simple fluid.²⁴⁸

Hemorrhagic cysts rarely exhibit the markedly shortened T1 and T2 commonly seen with endometriomas.³⁸⁰ In contrast, some endometriomas overlap in signal intensity with corpus luteum cysts.²⁵⁹ Small ovarian follicles normally stud the surface of ovaries of premenopausal women, and these are apparent on high-resolution MR images.^{215, 348}

Endometriosis

Endometriomas, also known as endometriotic cysts, are manifestations of advanced-stage endometriosis.⁴⁰¹ They

usually involve the ovaries and are bilateral in one third to one half of cases.^{64, 96} The wall of these cysts is usually thick and fibrotic, but it may be thin and attenuated. The cyst contains altered blood that varies from the usual viscous “chocolate” material to the much less common watery fluid.⁶⁴ Dense adhesions often fix the endometrioma to surrounding pelvic structures.

Although MRI studies demonstrate that endometriomas are reliably detected,^{11, 380, 420} MRI is insensitive, compared with laparoscopy, in overall detection and staging of endometriosis; it cannot accurately detect superficial implants and adhesions,¹¹ which are usually small and occur on peritoneal surfaces.

Figure 45-38. Adenomyosis. Sagittal T2-weighted, spin-echo (*A*) and axial T2-weighted (*B*) images demonstrate thickening of the junctional zone (arrowheads). Small, punctate, high-signal-intensity foci (arrows) represent endometrial glands. (From Outwater EK, Siegelman ES, Van Deerlin V: Adenomyosis: Current concepts and imaging considerations. *AJR Am J Roentgenol* 170: 437–441, 1998.²⁶³)

Figure 45-39. Endometrial polyp in a 31-year-old woman. Sagittal T2-weighted, fast spin-echo image shows the polyp (arrowheads) outlined by a small amount of fluid (thin white arrow). The thin fibrous core of the polyp (black arrow) can be seen. The mass shows no evidence of invasion of the junctional zone.

MRI criteria can reliably distinguish endometriomas from most other ovarian masses, including ovarian malignancies.^{375, 380} Endometriomas have variable appearances on T1-weighted and T2-weighted SE images, which differ, nonetheless, from simple (nonhemorrhagic) ovarian cysts.⁴²⁰ On T1-weighted images, homogeneously very hyperintense cysts that become relatively hypointense on T2-weighted sequences, or multiple cysts that are entirely hyperintense on T1-weighted sequences, indicate endometriomas in the appropriate clinical setting (Fig. 45-41).^{248, 380} MRI evidence of hemorrhage per se in a cystic mass is certainly not specific for a benign hemorrhagic cyst or endometrioma, since this feature is often seen in ovarian cystadenomas and carcinomas.^{234, 235, 376}

Togashi and colleagues³⁸⁰ listed MRI criteria that are helpful in the diagnosis of endometriomas, including:

1. A cystic lesion that is hyperintense on short TR/TE images and shows "shading," or relative hypointensity, on long TR/TE images.
2. The presence of multiple (more than two) hyperintense lesions on short TR/TE images.

Endometriomas may also be hyperintense on short TR/TE images and hyperintense without shading on long TR/TE images; however, this pattern of hyperintensity on T1-weighted and T2-weighted sequences is nonspecific and is

Figure 45-40. Ovarian cysts. A, Axial T1-weighted, spin-echo multicoll image (TR = 4000 msec, TE_{eff} = 126 msec) shows a large cyst of the right ovary (C) adjacent to a small, high-signal-intensity cystic lesion in the right ovary. B, T2-weighted, fast spin-echo image shows the typical high signal intensity of a simple ovarian cyst (C). The high-signal-intensity small cyst identified in A, however, shows slightly lower signal intensity on the T2-weighted image as well as a low-signal-intensity rim (arrowheads). This nonspecific appearance is compatible with a small endometrioma, which indeed was confirmed at surgery. C, Gadolinium-enhanced T1-weighted image obtained with fat saturation shows the thick, enhancing wall of the corpus luteum cyst (arrow). TE_{eff}, effective echo time.

Figure 45-41. Ovarian endometrioma. *A*, Axial T1-weighted spin-echo image (TR = 600 msec, TE = 12 msec) through the ovaries show a high-signal-intensity mass of the left adnexa (asterisk). *B*, T2-weighted fast spin-echo image (TR = 4000 msec, TE_{eff} = 140 msec; acquisition matrix = 256 × 256; field of view = 22 cm; slice thickness = 5 mm) shows marked low signal intensity (shading) within the mass (arrow), characteristic of an endometrioma. Several high-signal-intensity ovarian follicular cysts surround the mass, indicating its location within the ovary. TE_{eff}, effective echo time.

commonly seen in hemorrhagic cysts as well.²⁵⁹ These criteria exclude lesions with solid nodules, obvious septations, or very large size. Masses with signal intensity characteristics of hematomas are also excluded (see Fig. 45-51).

Applying these criteria in a prospective study, Togashi and coworkers³⁸⁰ were able to identify endometrial cysts with 90% sensitivity, 98% specificity, and 96% accuracy. No malignancies were misdiagnosed as endometriomas.³⁸⁰ Malignant transformation of endometriosis, although rare, may occur.¹¹⁷ Ancillary findings that are commonly seen in endometriomas include low-signal-intensity rims, caused by the hemosiderin and fibrosis in the wall, and tethering to surrounding structures.¹¹

Implants of endometriosis are sometimes seen on MR images.³⁰ These typically appear as nodules that show low signal intensity on T2-weighted images because of their dense fibrosis.³⁴¹ Punctate hemorrhage within them may be detected on fat-saturated, T1-weighted images.³⁶⁵ Dilated fallopian tubes containing fluid that shows high signal intensity on T1-weighted images are sometimes seen in patients with endometriosis.²⁶⁰

Pelvic Inflammatory Disease

Tubo-ovarian abscess is a complication of pelvic inflammatory disease. In acute pyogenic salpingitis, pus emanating from the fallopian tube becomes confined by pelvic adhesions to form an abscess. This abscess usually lies near or involves the ovary. Such abscesses appear on MR images as unilocular or multilocular cystic masses, usually with a thicker wall than that seen in functional ovarian cysts (Fig. 45-42).¹³⁰ The abscess fluid shows variable signal intensity but usually has very high signal intensity on T2-weighted images and low signal intensity on T1-weighted images.^{130, 235} Infiltration of pelvic fat surrounding the mass may be evident. Acute or chronic pelvic inflammatory disease is frequently accompanied by dilatation of the fallopian tube (see Fig. 45-52).^{260, 386} Analysis of

pyosalpinges or hydrosalpinges in more than one MRI plane may be necessary to recognize their tubal character.²⁶⁰

Puerperal ovarian vein thrombophlebitis is an uncommon complication of postpartum endometritis. The disorder usually presents in the puerperium with prolonged fever after an initial trial of antibiotic therapy for endometritis. Approximately 80% of cases occur on the right side, and the thrombus may extend into the inferior vena cava. Either CT or MRI may be used for diagnosis.^{181, 310, 387} Typically, the thrombus is slightly hyperintense on T1-weighted images and hyperintense on T2-weighted images.^{205, 310} Enlargement of the involved gonadal vein as well as surrounding inflammatory changes, seen as stranding, are typical.^{181, 387} Gradient-echo techniques easily demonstrate the absence of flow in the involved veins.^{181, 387}

Benign Ovarian Neoplasms

Mature cystic teratomas (*dermoid cysts*) are a common cause of adnexal masses, accounting for approximately 20% of all ovarian neoplasms. Almost all of these lesions have some component that demonstrates lipid characteristics on MR images (Fig. 45-43).^{42, 379} This lipid represents the liquefied space within the cysts and may also represent adipose tissue in the wall or nodules of dermoid cysts. These areas show signal intensity characteristics that approximate (but do not necessarily coincide with) the signal intensity of adipose tissue.³⁷⁹

For definite identification of this lipid, a chemical shift-selective technique should be used to differentiate these lesions from hemorrhagic lesions that may have similar signal intensity characteristics (see Fig. 45-43).^{108, 169, 358} The diagnosis of mature cystic teratomas may be confirmed when lipid structures are demonstrable within the mass.^{108, 169, 358} and is easily performed with frequency-selective presaturation or chemical shift-selective techniques.^{108, 169, 358} Although this finding is not absolutely specific for dermoid cysts, it virtually excludes a malignant tumor in a uterine or ovarian mass.⁸¹

Figure 45-42. Pelvic inflammatory disease with pyosalpinx. *A*, Axial spin-echo image (TR = 600 msec, TE = 17 msec) shows a left ovarian cystic mass and infiltration of fat near the left ovary and cul-de-sac (black arrow). *B*, Axial T2-weighted, fast spin-echo image (TR = 4000 msec, TE_{eff} = 126 msec) demonstrates the cystic nature of the ovarian mass and shows a second structure posteriorly (white arrow). *C*, Sagittal T2-weighted, fast spin-echo image (TR = 4000 msec, TE_{eff} = 120 msec) through this structure reveals it to be a dilated fallopian tube (white arrow). A small amount of cul-de-sac fluid is also seen. TE_{eff}, effective echo time.

Accounting for approximately 4% of ovarian neoplasms are (1) fibromas, (2) thecomas, (3) fibrosed thecomas, and (4) fibrothecomas.

Ovarian fibromas are important from an imaging standpoint because they appear as solid masses and therefore mimic malignant neoplasms. They are associated with ascites in 40% of cases, particularly in larger lesions, and with pleural effusions in a small percentage (Meigs' syndrome).^{6, 65} These tumors are composed of admixtures of fibrous tissue and theca cells with abundant lipid in the cytoplasm.

Fibromas show homogeneous intermediate to low signal intensity on T1-weighted MR images. On T2-weighted images, fibromas appear as well-circumscribed masses showing very low signal intensity with scattered high-signal-intensity areas that represent edema or cystic degeneration.^{258, 259} The very low signal intensity results from the abundant collagen content of these tumors. Because of their predominantly low signal intensity on T2-weighted images, fibromas display a relatively specific appearance on MR images.^{262, 384} *Brenner tumors*, another benign neoplasm, have a similar appearance because they have a dense fibrotic component.²⁶¹ Pedunculated leiomyomas also appear as low-signal-intensity masses (Fig. 45-44).

Benign forms of serous and mucinous tumor are common. Features more suggestive of benign cystic neoplasm include unilocularity of cysts, thin walls, minimal sep-

tations, and absence of papillary projections. Mucinous ovarian tumors represent 20% of all ovarian tumors.²⁶¹ They are generally cystic; unlike serous tumors, however, they may be very large and they tend to be multiloculated (see Fig. 45-14).²⁶² They often show variable signal intensity in the locules that results from proteinaceous or mucinous contents or hemorrhage.

In regard to cystadenofibromas, the fibrous component is part of the neoplasm, which is believed to be of epithelial and stromal origin, as are cystadenomas and cystadenocarcinomas.^{256, 261} Cystadenofibromas usually appear as multilocular cystic masses with a solid portion, and the fibrotic component of these masses shows very low signal intensity on T2-weighted images (see Fig. 45-1).²⁵⁸ These tumors are less likely to be borderline or malignant compared with other serous or mucinous tumors.

Obstetric Applications

MRI is ideally suited to the evaluation of pelvic masses in pregnant patients when ultrasound is nondiagnostic.^{8, 100, 400} MRI is reliable in detecting benign ovarian masses and in identifying dermoids and leiomyomas (see Fig. 45-44), including those that may interfere with delivery.^{8, 100, 400} Although adnexal masses are not uncommon in pregnant women, malignancies are rare. Ovarian carcinoma occurs

Figure 45-43. Large mature cystic teratoma in a 43-year-old woman. *A*, Sagittal T2-weighted fast spin-echo sequence (TR = 4800 msec, TE_{eff} = 98 msec) shows a large mass (M) filling the pelvis and displacing the uterus posteriorly. *B*, Axial T1-weighted, spin-echo image (TR = 433.3 msec, TE = 8 msec) shows a high-signal-intensity mass of the right ovary. Low-signal-intensity calcifications are evident (arrow). *C*, Axial T1-weighted, fat-saturated, gradient-echo image (TR = 400 msec, TE = 2.1 msec) shows saturation of the cyst contents. TE_{eff}, effective echo time.

Figure 45-44. Adnexal mass in a pregnant patient. A previous ultrasound examination had shown a large, complex, partially solid mass. *A*, Axial spin-echo image (TR = 700 msec, TE = 12 msec) shows the placenta (P) and a mass in the left adnexa (M). *B*, Axial T2-weighted, fast spin-echo image (TR = 3800 msec, TE_{eff} = 126 msec) demonstrates the gravid uterus with the anterior placenta (P) as well as the left adnexal mass (M). The low signal intensity of the mass is consistent with a pedunculated leiomyoma. Small areas of hemorrhagic infarction are evident within the mass. TE_{eff}, effective echo time.

in only 1 of 17,000 to 38,000 pregnancies.¹⁶⁰ Ovarian tumors are one tenth as likely to be malignant in pregnant women as in nonpregnant women.²⁶

Ultrasonography is the primary modality for evaluation of the gravid uterus. MRI may be useful in specific instances when ultrasound is equivocal, such as in cases of extrauterine pregnancy or in evaluation of placenta position.⁸ Additional applications awaited the development of single-shot FSE (or HASTE) sequences, which permitted relatively motion-free images of the fetus. Before the advent of these sequences, fetal imaging required that pancuronium be administered to the fetus via an amniocentesis needle to alleviate motion artifacts. No known adverse fetal effects occur; however, large-scale studies showing the safety of MRI in pregnancy have not been performed.¹⁶⁶

Single-shot FSE sequences are useful in imaging the fetus or placenta when ultrasound findings are equivocal. The display of fetal anatomy before 20 weeks of gestation is usually inferior to that of ultrasound because of the small size and motions of the fetus.^{194, 195} Single-shot FSE images show particular advantages over ultrasound when ultrasound is limited (e.g., in the setting of oligohydramnios and in late third trimester). MRI can demonstrate additional findings in fetuses with neurologic abnormalities, such as germinal matrix hemorrhages and agenesis of the corpus callosum (Fig. 45–45).^{176, 194, 195, 251, 291, 408} MRI is also useful in depicting the contents of diaphragmatic hernias and omphaloceles because the liver can easily be distinguished from the bowel.¹⁴⁴ Widespread use of single-shot FSE sequences for fetal imaging awaits research into the optimal indications for MRI in these patients.

Malignancies of the Female Pelvis

MRI has not yet achieved widespread use for staging of pelvic malignancies, partly because of its general unavail-

ability and, more important, because of a lack of controlled clinical trials demonstrating efficacy in well-defined clinical situations in which additional staging information will affect the outcome for the patient. Nonetheless, MRI realizes fairly high staging accuracy for gynecologic malignancies, and persuasive arguments can be made for its increased clinical use.^{61, 112, 136, 305}

Uterus

Cervical Carcinoma

Cervical epithelium can undergo a series of gradual histologic changes from progressively severe dysplasia to carcinoma in situ (CIS) and invasive carcinoma. The detection of this progress with screening and biopsy has led to marked reduction in the mortality rate from this disease in the last 50 years in the United States.^{9, 36, 52, 276, 299} The incidence of CIS is greater than that of invasive carcinoma by a ratio of 4:1, and the highest incidence occurs around age 30 years, about 10 to 15 years earlier than that of invasive carcinoma.

Invasive carcinoma spreads by direct extension to adjacent organs, the vagina, the pelvic wall, and the bladder and rectum. Failure to achieve control of the disease when it is local is a major cause of treatment failure in advanced disease.^{117, 151, 278, 404} Metastatic lymphadenopathy occurs commonly in the pelvic lymph nodes, but it also involves the periaortic chains in 17% to 29% of patients, including 5% to 27% of stage IB and IIA lesions.^{3, 117, 119, 185, 276, 390} Locally advanced tumors may also disseminate along the peritoneum.¹¹⁹

The 5-year survival rate for invasive carcinoma is 80% to 90% for stage I, 75% for stage II, 35% for stage III, and 10% to 15% for stage IV.¹²¹ The surgical approaches for early-stage carcinoma include total hysterectomy for stage IA and radical hysterectomy for stage IB and II, although

Figure 45–45. Single-shot, fast spin-echo imaging of a fetus to evaluate for severe hydrocephalus suspected on ultrasound. *A*, The image, in the sagittal plane relative to the mother but in the coronal plane relative to the fetus, demonstrates cerebrospinal fluid filling the right and left hemispheres (H). The cerebellum appears intact (arrow). The lungs (L) and liver (asterisk) are demonstrated. *B*, Preservation of some of the frontal lobe and temporal lobe on the right in a patchy distribution indicates hydranencephaly, not hydrocephalus. (From Outwater EK: Ultrafast MR imaging of the pelvis. *Eur J Radiol* 29:233–244, 1999.²⁵⁵)

the National Institutes of Health (NIH) consensus panel suggests equal efficacy of radiation and surgery for this group. Radiation therapy is employed for bulky stage II, stage IIB, stage III, and stage IV disease.^{121, 275, 276} Anterior or posterior exenteration may be indicated in some cases of stage IV disease with bladder or rectal involvement because of the risk of fistula formation after radiation treatment.¹²¹

The identification of cervical carcinoma on MRI is straightforward because the high-signal-intensity lesion contrasts with the very-low-signal-intensity cervical stroma on T2-weighted images (Fig. 45–46).^{173, 405} Areas of coagulative necrosis may appear as small foci of lower signal intensity within the tumor mass.³⁴³ The signal intensity of cervical carcinoma has a variable response to radiotherapy; tumors responding to therapy tend to lose signal intensity on T2-weighted images.^{92, 309} T1-weighted images fail to

reveal smaller lesions because of a lack of contrast between cervix and tumor. Hematometra is not uncommon in cervical carcinoma because of cervical obstruction or radiation-induced stenosis (Fig. 45–47).^{39, 325}

An important potential role for accurate noninvasive staging of cervical carcinoma exists because staging based on clinical examination with the patient under anesthesia with cystoscopy and proctoscopy (Table 45–4) is inaccurate when compared with pathologic findings.^{117, 119, 185, 278, 390} Surgical staging for clinical stages IIB to IV is not routinely performed, and it carries significant morbidity.^{119, 185, 305} Intraoperative findings of advanced-stage tumors result in aborting plans for hysterectomy in up to 12% of patients with clinical stage I disease.^{76, 185} Patients treated with radiotherapy alone may be understaged or overstaged, causing adverse effects on mortality.¹¹⁷ Therefore, if sufficient accuracy can be established, MRI may become a desirable

Figure 45–46. Cervical carcinoma, stage IIB. *A*, T1-weighted image shows cervical enlargement (T). No differentiation of tumor and cervical stroma is seen. *B*, Axial T2-weighted, fast spin-echo image shows high-signal-intensity tumor (T) arising from the left cervical lip and growing into the left parametrium (arrow). *C*, Sagittal T2-weighted, fast spin-echo image demonstrates the tumor (T) without invasion superiorly into the uterine corpus. The low-signal intensity of the posterior vaginal fornix (arrowhead) is identified. *D*, T1-weighted spin-echo axial image shows metastases to the left external iliac lymph nodes (arrows).

Figure 45-47. Vaginal and bladder invasion from cervical carcinoma.

A, T2-weighted, fast spin-echo image shows extensive tumor (T) infiltrating the cervix and lower uterine segment, with obstruction of the endocervical canal causing hematometra (H). Infiltration into the anterior vagina and the bladder wall (arrow) can be seen.

B, T1-weighted, spin-echo image at the level of the vagina shows tumor extending anterior to the bladder wall and producing effacement of the fat plane (arrow) between the vagina and the bladder.

C, T2-weighted, fast spin-echo image shows the infiltration of the normal lower-signal-intensity muscularis at the site of bladder invasion (arrow).

D, T2-weighted image at the level of the myometrium shows the tumor (T) invading the uterine corpus. Nodal metastasis (N) produces obstruction of the left external iliac vein.

62	—	—	95	Yu et al ⁴¹⁸

substitute for clinical examination using anesthesia and may be cost-effective.^{138, 143, 305, 416} Because small tumors tend to be limited to the cervix, it has been suggested that stage IB lesions greater than 2 cm may benefit from MRI but those smaller than 2 cm may not.^{138, 416}

Consistently high rates of accuracy for MRI staging of cervical carcinoma (see Table 45-4) have been documented in several studies. Overall, rates of 76% to 90% accuracy are reported.^{67, 104, 137, 172, 173, 381} MRI has no role in assessing most cases of cervical carcinoma (i.e., CIS and stage IA) because these lesions are not visible on the images.^{173, 196, 381} In one prospective study, no stage 0 or IA lesions in 27 patients were detected.³⁸¹ Larger lesions are easily appreciated, and accurate measurement of tumor volumes can be obtained.^{46, 196, 343} Tumor volume is an important prognostic predictor of failure after radiation therapy, although it does not directly affect clinical staging by the International Federation of Gynecology and Obstetrics (FIGO) system.^{46, 151, 278, 343}

The detection of parametrial spread relies on visualization of tumor invading the paracervical venous plexus. Invasion into the paracervical tissues can be excluded if a low-signal-intensity rim of cervical stroma surrounds the tumor.^{137, 173, 344, 381} If this rim becomes effaced, parametrial spread is likely.^{137, 173, 294, 344, 377, 381}

Bulky stage I tumors may displace the plexus laterally without invading it.^{60, 137, 228, 304, 344, 381} Tumors at the cervical lip that extend posterolaterally may protrude into the vaginal fornices; higher or anterior tumors extend directly into the parametria (see Fig. 45-46).¹³⁷ Advanced tumors grow along the sacrouterine ligaments and the cardinal ligaments to the pelvic sidewall.^{228, 396, 397} These features are best seen with side-by-side comparison of T1-weighted and T2-weighted sequences for differentiation of tumor, paracervical venous plexus, and fat, since tumor and fat on T2-weighted sequences may exhibit little contrast.^{344, 396, 397} Tumor invading the vaginal wall interrupts the thin, low-signal-intensity wall on T2-weighted sequences (see Fig. 45-47).^{60, 67, 104, 137, 228, 377, 381} Similarly, if the low-signal-intensity muscularis of the bladder or rectum is focally disrupted, spread into these organs is likely (see Fig. 45-58).^{67, 104, 137, 173}

The role of gadolinium enhancement in staging of cervical carcinoma is evolving. Preliminary studies have found similar information on enhanced T1-weighted images and T2-weighted images but an overall increase in staging accuracy with the enhanced images.³⁷⁴ In other studies, however, staging was not improved with administration of contrast material (see Fig. 45-58).^{110, 373, 385} Dynamic gadolinium-enhanced images show rapid enhancement of cervical tumors and may help in staging.^{1, 115, 391, 409} Analysis of dynamic images may have prognostic value and aid in predicting response to radiation by identifying better-perfused tumors.²¹³ Finally, dynamic enhanced studies are useful for identifying recurrent cervical tumor.^{114, 406}

A complete evaluation of patients with cervical carcinoma should include transverse T1-weighted images of the infrarenal periaortic and iliac lymph node chains to detect enlarged lymph nodes. Periaortic metastatic adenopathy increases the stage of the disease and indicates a poor prognosis (see Fig. 45-47).^{3, 117, 278} The assessment of lymph nodes in cervical carcinoma is probably comparable to that

obtained by CT.⁸³ Experience with CT, however, indicates that size criteria alone are not sufficiently specific or sensitive for metastases^{117, 119, 210} and must be supplemented by needle aspiration to provide diagnostic information.^{21, 112}

Endometrial Carcinoma

Endometrial carcinoma is a disease of menopausal or postmenopausal women, with a peak incidence at age 60 years.²⁰⁰ Because *in situ* cervical carcinoma, detected by screening, has been largely eradicated, endometrial carcinoma has become the more common invasive tumor in the United States, with 36,000 cases in 1998.^{71, 186} Many endometrial carcinomas, however, are surgically curable while confined to the uterus, and the mortality rate is lower than that of invasive cervical carcinoma.¹⁸⁶ Risk factors include diabetes, hypertension, and disorders associated with prolonged unopposed estrogen stimulation (i.e., obesity, nulliparity, infertility, estrogen-secreting tumors, and exogenous estrogen administration).^{71, 299}

Endometrial carcinoma tends to proliferate within the endometrial cavity as a localized polypoid mass or as a diffuse tumor involving the entire endometrial surface.²⁹⁹ Initially, invasion occurs through the myometrium or into the endocervical canal. Pelvic or periaortic lymph node metastases and peritoneal metastases ensue with advanced tumors.^{37, 239, 299} although these can occur with stage I disease.^{37, 299} Endometrial carcinoma may metastasize to the adnexa or vagina, although frequently in microscopic deposits.^{37, 239}

The most common MRI finding in patients with small endometrial carcinomas is widening of the endometrial cavity due to the tumor or associated hematometra (Fig. 45-48).^{42, 130, 140, 369, 405} MRI scans are normal in 15% to 19% of patients with endometrial carcinoma because small superficial lesions blend in with the normal endome-

Figure 45-48. Endometrial carcinoma with hematometra. Sagittal T2-weighted image (TR = 5833 msec, TE_{eff} = 126 msec) shows the uterine and endocervical canals to be markedly distended with hemorrhagic fluid (H). The irregular tumor (arrowheads) lines the endometrial cavity. TE_{eff}, effective echo time.

trium.^{139, 140} Masses of tumor within the endometrial cavity display variable signal intensity on T2-weighted images,^{140, 405} but they exhibit higher intensity than the uterine junctional zone or myometrium (see Fig. 45–48).^{103, 139, 140, 209, 285, 413} Considerable signal heterogeneity due to necrosis, hemorrhage, and endocervical canal obstruction by hematomata is evident with larger tumors on T2-weighted images.^{130, 369, 376} Gadolinium enhancement easily distinguishes vascularized tumor from areas of nonenhanced necrosis or fluid accumulation.^{110, 130, 376} Usually, tumor enhances somewhat less than myometrial tissue, although the tumor-myometrial interface is often obscured by gadolinium (Figs. 45–49 and 45–50).¹³⁵

The clinical usefulness of preoperative radiologic staging of endometrial carcinoma is not established.^{209, 240, 305} Endometrial carcinoma is definitively staged using the surgical FIGO system.^{71, 394} Treatment decisions are made, in part, on the basis of lymph node sampling or an assessment of relative risk for occult lymph node metastases.^{37, 44, 71, 165, 208, 239, 240} The risk factors for periaortic nodal metastases in stage I or II disease include depth of myometrial invasion, presence of adnexal metastases, tumor grade, and grossly positive lymph nodes, all of which may be determined intraoperatively.^{37, 44, 71, 162, 165, 202, 208, 239, 247} Furthermore, lymphadenectomy may confer survival benefit.¹⁷⁰ The role of preoperative radiation (e.g., intracavitary treatments) is unclear, although less toxicity to bowel may ensue than with postoperative radiotherapy.^{44, 202, 247} MRI may be useful to plan radiation treatment portals.³⁰⁵

Staging of endometrial carcinoma by MRI requires the following:

1. Demonstration of the tumor's relationship to the myometrium and cervix.

2. Clear demonstration of the boundaries between the uterus and the bladder, rectum, and vagina.
3. Assessment of lymph nodes from the level of the kidneys through the pelvis.

T2-weighted sagittal images display the uterine anatomy to best advantage and are considered most essential for showing intrauterine invasion. Transverse T1-weighted images are adequate for the evaluation of lymphadenopathy. The myometrium enhances intensely and rapidly on dynamically enhanced images, whereas endometrial adenocarcinomas enhance poorly. Differentiation between myometrium and invading tumor may be better in some cases on enhanced images than on T2-weighted images.

The depth of myometrial invasion is one of several pathologically defined risk factors that correlate with the surgical stage of disease, presence of lymph node metastases, and prognosis.^{37, 44, 162, 202, 208, 239} The most reliable sign of myometrial invasion on MR images is focal discontinuity in an otherwise discrete junctional zone.^{139, 140, 282, 285, 376, 413} A distinct junctional zone, however, is not always visualized in postmenopausal women.³²⁷ Enhanced images, particularly dynamically enhanced images, may show better differentiation between myometrium and tumor in these patients than T2-weighted images (see Fig. 45–50).³³¹

A second sign is focal thinning of the myometrium or irregularity of the tumor-myometrial interface (see Fig. 45–7).¹⁴⁰ Larger tumors and hematomata frequently thin the myometrium concentrically; therefore, this is a nonspecific finding.^{140, 376}

The prospective accuracy of determination of invasion depth has been reported to be 74% to 94%.^{27, 63, 103, 139, 140, 327, 369, 413} Studies suggest better accuracy with MRI for determination of myometrial invasion depth than with ultrasound or CT.^{174, 175}

Figure 45–49. Obstructed uterus caused by endocervical adenocarcinoma. A, Sagittal T2-weighted, fast spin-echo (FSE) image (TR = 6000 msec, TE_{eff} = 119 msec) shows a hematoma (asterisk) caused by an irregular intermediate-signal-intensity tumor (white arrows) obstructing the end of the cervical canal. Because of tumor infiltration, the normal low signal intensity of the cervical stroma is entirely disrupted and the junctional zone in the low uterine segment is irregular and disrupted. The vaginal wall is irregularly thickened (open arrow). B, Sagittal gadolinium-enhanced image corresponds to the same level as in A. The endocervical canal tumor enhances, although not as much as the normal myometrium, and the hematoma (asterisk) does not enhance. The thickened enhancing tissue along the anterior vaginal wall indicates vaginal wall invasion. TE_{eff}, effective echo time.

Figure 45-50. Advanced endometrial carcinoma. *A*, T1-weighted spin-echo image shows a large uterine mass (M) with parametrial spread and thickening of the uterosacral ligaments (arrows). *B*, Sagittal T2-weighted, fast spin-echo image shows tumor causing full-thickness disruption of the myometrium (arrows). Invasion into the cervix (arrowhead) and fluid in the uterine corpus result from obstruction of the lower uterine segment. *C*, Dynamic gadolinium-enhanced image shows enhancement of the tumor with focal lack of enhancement (arrows) of the myometrium, indicating full-thickness penetration of the myometrium.

Invasion of the cervix can be confirmed by MRI when high-signal-intensity tissue expands the endocervical canal or, more reliably, when tumor disrupts the low-signal-intensity cervical stroma (see Fig. 45-50).^{27, 139, 140, 376} These findings are generally easily appreciated by MRI.^{63, 140} Reported accuracies for the detection of cervical invasion are 85% to 90%.^{27, 369}

Determination of stage III or IV disease requires assessment of the adnexa, uterine and cervical suspensory ligaments, pelvic lymph nodes, and bladder and rectal walls.^{139, 140, 376} MRI findings indicative of advanced disease include transmural interruption of the myometrium, serosal irregularity, and disruption of the low-signal-intensity vaginal, bladder, or rectal muscularis.^{63, 139, 140, 376} Adnexal metastases, which are not uncommon, may be confused with normal high-signal-intensity ovaries or other ovarian abnormalities.^{63, 84}

In one prospective study, the sensitivity for the detection of stage III or IV disease by MRI was only 17% and the positive predictive value for findings suggestive of advanced tumor was only 50%.¹³⁹ The accuracy of MRI staging of endometrial carcinoma has been reported to be

85% overall.^{139, 369} Gadolinium-enhanced images significantly improve accuracy.^{159, 175, 311, 345, 407}

Uterine Sarcomas

In addition to arising from the endometrium, uterine malignancies may originate from endometrial stroma (stromal sarcoma), pluripotential mesoderm (müllerian mixed mesodermal tumors), and myometrial smooth muscle (leiomyosarcomas).²⁹⁹ Unlike endometrial carcinoma, mesenchymal malignancies often remain undetected by screening techniques and tend to be in an advanced stage at diagnosis. Spread by either the lymphatic or the hematogenous route is more likely at presentation compared with endometrial carcinoma.^{17, 59, 62, 336}

Müllerian mixed mesodermal tumors are aggressive malignancies with a propensity for advanced stage at diagnosis.^{17, 31, 299} Their biologic behavior and MRI characteristics are otherwise similar to those of endometrial carcinoma.^{336, 376}

Tumors derived from endometrial stromal tissues include benign stromal nodules, low-grade stromal sarcoma

(indistinguishable from benign nodules but with lymphatic invasion), and endometrial stromal sarcoma (Fig. 45-51).¹⁷ These tumors show intermediate to high signal intensity and infiltrate into the myometrium or vessels, an appearance dissimilar from that of leiomyomas.¹⁷⁹

Leiomyosarcomas arise from myometrial smooth muscle and usually occur in women between ages 40 and 60 years. Histologically, sarcomas are difficult to differentiate from leiomyomas; typical criteria include more than 10 mitoses per high-powered field or more than 5 mitoses with nuclear atypia per high-powered field.^{17, 299} Given this subtle difference, it is unlikely that MRI will prove useful in differentiating between the two, although it serves to identify the myometrial origin of these tumors.^{136, 152} A large size at presentation and heterogeneously increased signal on T2-weighted images distinguish sarcomas from most, but certainly not all, leiomyomas.^{136, 152, 267, 354} MRI may prove useful in the unusual venoinvasive form of this sarcoma (intravenous leiomyomatosis) to demonstrate the extent of intravascular disease.³³⁹

Gestational Trophoblastic Disease

Gestational trophoblastic disease forms a spectrum of related conditions, which include molar pregnancy, invasive mole, and choriocarcinoma. After evacuation of a complete mole, persistent gestational trophoblastic disease develops in 20% of patients, and metastases occur in 5%.²⁸ Chemotherapy achieves a high rate of cure even when the tumor is widely metastasized.²⁸ The role of radiologic evaluation of patients with gestational trophoblastic disease lies primarily in the identification of metastases in the lung, brain, and liver.^{28, 145}

MRI may be useful in demonstrating intrapelvic spread and tumor size. The signal intensity pattern of gestational trophoblastic disease is variable. Intratumoral hemorrhage frequently causes high-signal-intensity areas on T1-weighted sequences (Fig. 45-52).^{132, 376} Heterogeneity on T2-

Figure 45-51. Uterine sarcoma. Axial T2-weighted, fast spin-echo multicoil image demonstrates heterogeneous intermediate signal intensity and a mass (M) arising from the posterior uterine wall. Continuity of the mass within the myometrium can be seen (arrows). The mass has internal necrosis, and no part of it displays the usual low-signal-intensity areas of a uterine leiomyoma. Pathologic examination showed an endometrial stromal sarcoma.

weighted sequences results from necrosis, hemorrhage, and cyst formation.^{61, 132, 230} Large uterine vessels supplying the tumor appear as peritumoral signal voids.^{132, 230} Metastases to the vagina occur in 16% to 30% of cases.^{28, 145} Theca lutein cysts, which are frequently hemorrhagic,⁶¹ occur in 30% to 50% of cases.^{28, 132}

Uterine Adnexa

Malignant Ovarian Neoplasms

Ovarian carcinoma causes more than twice as many deaths as any other pelvic gynecologic malignancy.¹⁸⁶ The incidence of epithelial ovarian carcinoma rises steadily between ages 30 and 70 years.¹⁶⁷

More than 20 histologic types of tumors arise from the ovary. The origin of these neoplasms may be (1) surface ovarian epithelium, (2) germ cells, and (3) sex cord-stromal.²⁹⁹

Most malignant ovarian neoplasms in women are epithelial, including serous carcinomas, mucinous carcinomas, endometrioid carcinomas, and clear cell carcinomas.²⁹⁹ These four neoplasms share similar clinical manifestations, frequency of bilaterality (20% to 40% of cases), propensity for intraperitoneal metastasis, and a poor prognosis.^{167, 299} Low-grade forms, termed *borderline* or *low malignant potential tumors*, have a markedly better prognosis (>90% 5-year survival) than higher grades.²⁹⁹ Endometrioid and clear cell carcinoma resemble endometrial carcinoma histologically and may coexist with endometriosis and synchronous endometrial carcinoma.²⁹⁹ Clear cell carcinoma demonstrates a poorer prognosis and higher rates of lymphatic and hematogenous metastasis.¹⁵³ Epithelial carcinomas, indistinguishable from those of ovarian origin, may arise in the peritoneum without ovarian involvement.⁴

In MRI evaluation of an adnexal mass, the first step is to establish that the mass arises from the ovary. High-resolution, T2-weighted images are necessary to identify the ovaries and their relationship to the mass. Heavily T2-weighted FSE images identify small follicular cysts stretched around a mass, thus establishing an ovarian mass. Gynecologic masses of other origin (e.g., peritubal cysts, dermoid cysts, pedunculated fibroids, endometriomas, and hydrosalpinges) must be distinguished from malignancies.

Fairly high accuracy rates for distinguishing benign from malignant ovarian tumors by MRI have been reported, although it is unclear whether this is sufficient for clinical management in difficult cases. MRI features that suggest malignancy in an adnexal mass include the following (Fig. 45-53)^{49, 346, 359, 373}:

- Size greater than 4 cm
- Irregular or large solid components in a cystic mass
- Thick (>3 mm) septations
- Evidence of peritoneal, lymphatic, or hematogenous spread or local invasion

Papillary projections within an ovarian mass establish that the mass is an ovarian neoplasm, although projections may also be seen in benign (uncommon), borderline (common), and higher-grade malignant lesions (Fig. 45-54; see Fig. 45-53). When these and other criteria described previously are used, accuracies of 60% to 93% for distinguishing benign from malignant masses have been reported for

Figure 45-52. Gestational trophoblastic disease. T1-weighted (A) and T2-weighted (B) images show a high-signal-intensity mass embedded within the myometrium (*white arrows*) in a patient after evacuation of a complete mole. On the T2-weighted, spin-echo image in B, the punctate signal voids around the mass (*arrowheads*). A multiseptate theca lutein cyst is present.

Figure 45-53. Borderline ovarian serous tumor in a 40-year-old woman.

A, T1-weighted, spin-echo image shows a left ovarian mass (C) with slightly high signal intensity of the cyst fluid. The normal right ovary (*arrow*) shows intermediate signal intensity, similar to that of the uterus.

B, T2-weighted, fast spin-echo image shows the normal right ovary (*arrow*) with small cystic follicles. The left serous tumor has the high signal intensity of the cyst fluid, with small papillary projections (*arrowheads*).

C, Gadolinium-enhanced, T1-weighted, fat-suppressed gradient-echo image shows enhancement of the papillary projections (*arrowheads*). The normal ovary (*arrow*) enhances less than the uterus.

(A, From Ascher SM, Outwater EK, Reinhold C: Adnexa. In Semelka RC, Ascher SM, Reinhold C [eds]: MRI of the Abdomen and Pelvis: A Text-Atlas. New York, Wiley-Liss, 1997, pp 661–715.¹² B and C, From Outwater EK, Mitchell DG: Normal ovaries and functional cysts: MR appearance. Radiology 198:397–402, 1996.²⁵⁷)

Figure 45-54. Papillary projections in a patient with a borderline ovarian serous tumor. *A*, Sagittal T2-weighted, fast spin-echo image (TR = 6000, TE_{eff} = 119) shows a multicystic left adnexal mass (arrowheads). Within this mass is an ill-defined projection with a low-signal-intensity core (arrow). *B*, Sagittal T2-weighted, fat-saturated, gradient-echo image (TR = 250, TE = 2.9) shows enhancement of the papillary projection (arrow). Many of the papillary projections show very high signal intensity, blending in with the fluid within the cyst in *A*. TE_{eff}, effective echo time.

MRI,^{346, 359} and higher accuracies have been reported with Gd-DTPA enhanced images.^{359, 373} An accuracy rate of 86% has been described for distinguishing benign from malignant epithelial neoplasms.⁹⁸ These rates are comparable to those of 80% and 94%, respectively, reported for CT and ultrasound.⁴⁹ One comparative study established a higher accuracy rate for differentiating benign from malignant ovarian masses with MRI compared with transvaginal ultrasound and Doppler analysis (Table 45-5).¹⁸⁴

The signal intensity of cystic components of ovarian neoplasms varies, especially in mucinous tumors.^{98, 209, 234, 376} Specifically, the signal may be hyperintense on T1-weighted images and intermediate on T2-weighted images because of hemorrhage, mucin content, or cell debris (see Fig. 45-14).^{98, 234, 235, 376, 380} Gd-DTPA can assist in defining nodules, fluid loculi, and septa in complex adnexal masses (Fig. 45-55; see Fig. 45-54).^{98, 110, 359, 370}

Unlike endometrial and cervical carcinomas, ovarian carcinoma is usually diagnosed only after it is not surgically curable. About 30% of ovarian carcinoma (stage I and IIa disease) is surgically resectable by total hysterectomy

and salpingo-oophorectomy. Optimal debulking of metastatic disease confers survival benefit.^{35, 40, 284, 388}

Hysterectomy, salpingo-oophorectomy, omentectomy, and peritoneal inspection and washings constitute the definitive staging procedure for ovarian carcinoma.^{43, 167, 297} Radiologic staging is inadequate primarily because of the high rates of microscopic peritoneal deposits throughout the abdomen.⁴³ Ascites is a nonspecific feature, and as few as 40% of patients with ascitic fluid exhibit positive findings in cytologic examinations of the peritoneum.⁴³ In second-look examinations, even laparotomy may have a 20% false-negative rate.⁹⁷ These observations limit the application of CT as a substitute for surgical staging or restaging of ovarian carcinoma.^{107, 112, 158, 223} Similarly, MRI has no defined role in staging or in second-look evaluations during therapy. Preliminary results, however, suggest that accuracy rates of up to 75% may be achieved with contrast-enhanced MRI staging of ovarian carcinoma³⁵⁹ and of 83% for detection of recurrent disease.²⁷⁰

In any case, recognizing macroscopic intra-abdominal spread of ovarian carcinoma is crucial during MRI evaluation of these patients. Solid or cystic peritoneal nodules can be identified in many cases;⁹⁸ in this regard, glucagon helps to suppress motion artifacts from bowel. The characteristic appearance of "omental cake" can be identified by its infiltrative margins and is distinguished from bowel by Gd-DTPA enhancement if necessary.¹³⁰ Gadolinium-enhanced, T1-weighted images with fat-suppression techniques may be particularly helpful in defining peritoneal spread (Fig. 45-56).^{199, 264, 333}

Complications of Radiation and Surgery

MRI can demonstrate common postoperative complications in the pelvis. Hematomas, lymphoceles, abscesses, fistulas, and venous thromboses can be detected and charac-

Figure 45-55. Clear cell carcinoma in a 51-year-old woman. *A*, Sagittal T2-weighted, fast spin-echo image shows a large, primarily unilocular cystic lesion with peripheral masses (M). *B*, Axial T2-weighted image shows the dominant solid nodule (M), an appearance characteristic of clear cell carcinoma.³⁷⁵ *C*, Gadolinium-enhanced T1-weighted, fat-suppressed, spoiled gradient-echo image shows that the nodule enhances following contrast. The uterus (u) is displaced anteriorly. (From Ascher SM, Outwater EK, Reinhold C: *Adnexa*. In Semelka RC, Ascher SM, Reinhold C [eds]: *MRI of the Abdomen and Pelvis: A Text-Atlas*. New York, Wiley-Liss, 1997, pp 661–715.¹²)

terized by MRI.¹³⁰ Fluid collections with peripheral hyperintense rims (*ring sign*) on T1-weighted images characterize hematomas.¹³⁰ Lymphoceles develop after lymphadenectomy; they manifest as sharply marginated cystic masses along the lymphatic chains and contain simple fluid.^{130, 404} Gadolinium enhancement of a mass with central fluid signal intensity and infiltrative borders characterizes most abscesses in the postoperative period.^{128, 130}

Fistulas are common complications after radiotherapy of larger gynecologic neoplasms and after surgery.¹⁸² Enterovaginal and vesicovaginal fistulas are the most common types in this context.¹⁸² Fistulous tracts on T2-weighted MR images appear as tracts of fluid signal intensity surrounded by lower-signal-intensity granulation tissue and fibrosis (Fig. 45–57).

External beam radiotherapy induces a number of changes in normal structures in the pelvis that are evident on MR images. Fascial and muscle edema; thickening of and edema in the walls of the rectum, bladder, and vagina; and fatty infiltration of bone marrow are all seen on MR images.^{32–34, 361} Radiation effects depend on the radiation dose and the time elapsed since radiotherapy. Increased

signal intensity on T2-weighted images usually reflects acute or subacute changes and does not persist indefinitely.^{10, 89, 361} Increased signal intensity should not be confused with tumor recurrence.^{10, 60} Bladder and rectal mucosal changes correlate, in part, with radiation cystitis and proctitis.³⁶¹

The differentiation of recurrent pelvic carcinoma from postoperative fibrosis is a common clinical problem to which MRI has been applied. Recurrent tumor in the pelvis usually appears as nodules or masses with higher signal intensity than fibrosis on T2-weighted images (Fig. 45–58),^{89, 101, 102, 149} although exceptions may occur.⁷⁵ Infiltrative recurrences without definable mass are not common.⁸⁹ Fibrotic scarring less than 6 months old shows slightly higher signal intensity than late fibrosis (>1 year) and overlaps in signal intensity with tumor recurrences.^{89, 149} The surgical vaginal cuff and pelvic sidewall are common sites of recurrence of cervical and endometrial carcinoma^{94, 151, 404}; the incidence varies with the type of radiation given.^{151, 239, 404} An accuracy of 80%, with a sensitivity of 82% and a specificity of 78%, has been reported for the MRI determination of recurrent cervical carcinoma.⁴⁰⁴

Figure 45-56. Marked ascites and bilateral ovarian surface implants of papillary serous carcinoma (*arrowheads*). *A*, T2-weighted, fast spin-echo image shows the normal fallopian tubes (*thin arrows*) attached to the broad ligaments (*open arrows*) by the thin mesosalpinges. *Arrowheads* point to implants of papillary ovarian cancer coating the surfaces above the ovaries. *Hatched arrow* points to nodular implants of papillary tumor in the cul-de-sac. *B*, Gadolinium-enhanced, T1-weighted, gradient-echo image demonstrates enhancement of the papillary tumor on the surface of the ovaries (*arrowheads*) and in the cul-de-sac (*hatched arrow*). (From Ascher SM, Outwater EK, Reinhold C: Adnexa. In Semelka RC, Ascher SM, Reinhold C [eds]: MRI of the Abdomen and Pelvis: A Text-Atlas. New York, Wiley-Liss, 1997, pp 661–715.¹²)

Figure 45-57. Rectovaginal fistula. Sagittal T2-weighted, fast spin-echo (*A*) and gadolinium-enhanced, fat-saturated (*B*) images in a patient after radiation for cervical carcinoma in whom fistula was not suspected at MRI. *A*, A high-signal-intensity tract (*white arrows*) extends from the rectum into the vaginal fornix. Although the posterior rectal wall is well delineated (*black arrows*), a defect in the anterior rectal wall leads into the fistula. *B*, The tract is nonenhancing (*arrowheads*). Incidentally noted are radiation changes in the spine and presacral space.

Figure 45-58. Tumor recurrence in a patient after proctectomy for rectal carcinoma. *A*, Axial T1-weighted image shows a presacral mass (arrows) with slightly more fullness on the right than on the left. *B*, Axial T2-weighted image shows an intermediate signal intensity to the fuller area on the right (arrow), whereas some of the presacral tissue consists of edema and low-signal-intensity scarring (arrowheads). Sagittal T1-weighted, fast spoiled gradient-echo images before (*C*) and after (*D*) administration of gadolinium show rapid enhancement of the nodular area (arrow), indicating recurrent rectal tumor.

Disorders of pelvic floor relaxation from obstetric and other trauma can be evaluated with MRI. Focal defects in the levator can be identified (Fig. 45-59). Although MRI can easily identify cystoceles, rectoceles, and uterine prolapse, these disorders can be quantified clinically.³⁹⁹ Enterocoeles, however, are difficult to identify on clinical examination, and MRI easily identifies these. Dynamic imaging with straining can reveal organ prolapse not evident on static images.^{68, 392}

Summary

MRI can delineate anatomy and pathology within the pelvis with higher intrinsic soft tissue contrast than ultrasound or CT, allowing better characterization of lesions and their relationship to surrounding organs. MRI has been useful in the diagnosis of some of the more common

gynecologic pelvic masses, although in both the male and female pelvis most attention has focused on the potential for MRI to stage, rather than to diagnose, neoplasms. Currently, MRI has the greatest accuracy and potentially the greatest clinical usefulness in staging cervical carcinoma. MRI can also be used to stage endometrial carcinoma with reasonable accuracy, but the clinical indications for preoperative endometrial carcinoma staging are less clear. Initial experience with bladder and rectal carcinomas is encouraging, although MRI is not clearly better than CT for clinical staging. MRI has proved to be somewhat disappointing, however, for staging of prostate cancer.

Many of the problems inherent in staging of tumors by MRI are common to all staging modalities and arise from as yet suboptimal tumor tissue contrast, low image resolution, and an inability to distinguish benign from malignant lymphadenopathy. More recent techniques, such as surface

Figure 45-59. Pelvic floor relaxation in a 77-year-old woman with a history of obstetric trauma. A, T2-weighted, fast spin-echo image (TR = 4000, TE = 98) shows attenuation of the right puborectalis (black arrow) on the right compared to the left (open arrow). B, Sagittal T2-weighted image shows a cystocele (hatched arrow) projecting inferiorly below the pubococcygeal line (dotted line).

coil arrays, FSE sequences, endoluminal coils, and new contrast agents, are contributing to the rapid pace of technological advancement in the field of MRI of the pelvis.

Musculoskeletal Tumors

Amilcare Gentili

Skeletal Tumors

Many imaging modalities are available for the evaluation of skeletal lesions. In most cases, standard radiographs are sufficient for detecting skeletal tumors⁹⁷; when evaluated together with clinical data (e.g., age, sex, anatomic location, clinical presentation), radiographs are the best predictors of the histologic condition of the lesion. To fully characterize a tumor in an anatomically complex area, such as in the spine, scapula, or pelvis, or in a periarticular location, however, magnetic resonance imaging (MRI) or computed tomography (CT) is often necessary.

Bone scintigraphy is the modality of choice for screening for skeletal metastases. Although MRI is more sensitive than scintigraphy in detecting metastases, it is not an efficient technique for evaluating the entire skeleton.³²

As stated, plain radiographs may be sufficient for diagnosis, but MRI and CT are fundamental in staging skeletal tumors. Optimal treatment of primary skeletal neoplasms in the absence of distant metastases includes complete surgical resection of the tumor. In the past, amputation was the treatment of choice. With improved surgical technique and aggressive chemotherapy, limb-sparing operations can be performed without affecting survival and with better functional results. In planning resection, accurate preoperative staging is essential. The initial CT or MRI procedures should be performed before biopsy because later it is often difficult to distinguish tumor from edema, hemorrhage, and granulation tissue.

Numerous studies have compared the usefulness of CT and MRI in the staging of musculoskeletal tumors.* MRI is superior for determining muscle compartment and vascular involvement because of the intrinsic contrast between tumor mass, muscle, and fat, without the need for enhancement with contrast medium. In addition, MRI is able to produce images in multiple planes, allowing easier assessment of intramedullary extent of tumor and intra-articular extension.²⁴ CT is superior for detecting subtle cortical invasion and periosteal and endosteal reaction and for depicting matrix calcification or ossification. Both MRI and CT are useful in evaluating the response to chemotherapy and radiation therapy.^{42, 102} Signs of response to treatment are (1) decreased tumor size, (2) improved delineation of the mass, (3) reappearance of fat planes between muscle groups, and (4) calcification or ossification of the tumor.

Technique

Computed Tomography

After a scout view, axial CT images are obtained with a slice thickness ranging from 1.5 to 10 mm, depending on the size and location of the tumor. Thin-section imaging should be used for small lesions. For evaluation of bone lesions, images are reconstructed using bone algorithms, images are reviewed using both bone and soft tissue window settings. Intravenous (IV) administration of a contrast agent aids in visualizing major vascular bundles and in assessing the vascularity of a lesion, and it may be helpful in distinguishing necrotic from viable tumor.

Magnetic Resonance Imaging

Numerous pulse sequences are available for the evaluation of musculoskeletal tumors, including (1) spin-echo and fast spin-echo, (2) inversion recovery, (3) gradient-echo, and (4) chemical shift sequences. My routine protocol for the evaluation of musculoskeletal masses includes images in at least two planes: usually (1) a T1-weighted sequence in the sagittal or coronal plane, followed by (2) either a double-echo (proton-density and T2-weighted), spin-echo sequence or a T2-weighted, fat-saturated, fast spin-echo sequence in the axial plane. A short tau inversion recovery (STIR) sequence is occasionally obtained to increase the conspicuity of a lesion.⁹⁴

Whenever possible, imaging is performed with a *surface coil* for enhanced spatial resolution and an improved signal-to-noise ratio. *Body coils* are used when an entire bone or soft tissue region is to be evaluated for the detection of skip lesions or for surgical planning. The use of contrast-enhanced MRI for the characterization of musculoskeletal tumors has yielded controversial results^{30, 83, 95} and is not routinely used in the musculoskeletal system.

Benign Skeletal Tumors

Enchondroma

An enchondroma is a common benign primary osseous tumor; its frequency follows only that of nonossifying fibromas and exostosis. There is no sex predilection, and approximately 50% of these tumors occur in the hands. They are asymptomatic unless they are undergoing malignant transformation or the bone is fractured, and they are often an incidental finding on radiographs.

Enchondromas are typically round or oval lesions with

* See References 1, 5, 9 to 12, 36, 76, 78, 96, 97, 108, and 113.

well-defined, lobulated borders. The unmineralized matrix exhibits soft tissue attenuation on CT scans, and homogeneous high signal intensity appears on T2-weighted MR images. Calcification with a ring and arc appearance, which suggests a chondroid matrix,^{2, 18} is best identified on plain radiography and CT. Calcifications are not consistently identified with MRI; when seen, however, they have low signal intensity on all sequences.

Benign and malignant chondroid lesions can have a similar appearance, making differentiation of an enchondroma from a low-grade chondrosarcoma difficult or impossible. The presence of a soft tissue mass or a cortical erosion or pain in the absence of fracture, however, increases the likelihood of malignancy.^{24, 74}

Chondroblastoma

Chondroblastoma is a benign rare tumor of cartilaginous origin composed of chondroblasts. Its peak incidence is in individuals between 10 and 20 years of age. It is more common in males, with a male-to-female ratio of 2:1.

Chondroblastoma involves the epiphysis, the apophysis, or both but may extend into the metaphysis after destroying the growth plate.⁴³ CT accurately demonstrates the extent of the lesion as well as matrix calcifications and subtle cortical infractions. Extension through the growth plate, however, is best detected with conventional tomography or MRI because the growth plate is usually best visualized in the sagittal or coronal plane. Both T1-weighted and T2-weighted MR images demonstrate a peripheral rim of signal void that corresponds to the sclerotic margin of the

lesion.⁴⁸ Abnormal signal intensity in large areas of bone marrow surrounding the lesion has been seen and probably represents bone marrow edema.^{15, 40, 105, 110}

Osteochondroma

Osteochondromas (exostoses) are the second most common benign tumor of bone after nonossifying fibromas. The male-to-female ratio is 1.5:1 to 2:1. These are congenital lesions but are usually discovered between 10 and 20 years of age. Multiple exostoses are uncommon, occurring only one tenth as frequently as a solitary exostosis, but they manifest earlier, usually before 10 years of age.

Ninety percent of osteochondromas originate from a long bone close to the metaphysis. The most common locations are around the knee (distal femur and proximal tibia) and the proximal humerus. The morphology of an osteochondroma is more important than the signal intensity in diagnosis. The incidence of malignant transformation is approximately 1% for solitary osteochondromas and from 5% to 25% for hereditary multiple exostoses.

Both CT and MRI demonstrate the continuity of the cortex and medullary cavity of the osteochondroma with that of the parent bone (Fig. 46-1).⁸⁷ The perichondrium is well seen on T2-weighted MR images as an area of low signal intensity surrounding the outer surface of the high signal intensity of the cartilage cap.⁵⁹ MRI measurements of cartilage cap thickness are also accurate, whereas CT measurements of maximal cartilage thickness are often imprecise.⁴⁴ The thickness of this structure is important in distinguishing benign osteochondroma from an exostotic

Figure 46-1. Osteochondroma presenting as a palpable mass in a 9-year-old boy. A, CT scan of the proximal humerus demonstrates continuity of the cortex and medullary cavity of the osteochondroma with that of the humerus, but the cartilage cap is not seen. B and C, Axial spin-echo image (B) (TR = 2400 msec, TE = 20 msec) and coronal spin-echo image (C) (TR = 2100 msec, TE = 90 msec) of the humerus clearly demonstrate the cartilage cap as an area of high signal intensity.

chondrosarcoma. According to most authors, the cartilage cap is usually thicker than 3 cm in a chondrosarcoma.⁵²

Other complications of osteochondromas include nerve injuries, vascular injury, and bursa formation.^{24, 68, 79} The formation of a bursa over an osteochondroma is common, and the bursa is usually asymptomatic; if it becomes inflamed and distended, it can be painful. On T2-weighted images, bursal fluid has high signal intensity similar to that of the cartilage cap, and it can be difficult to differentiate between the two. On gradient-echo sequences, cartilage has a lower signal intensity than that of fluid, and the diagnosis can be easily made. A rarer complication is the formation of a pseudoaneurysm adjacent to the exostosis.⁸¹

Chondromyxoid Fibroma

Chondromyxoid fibroma is composed of three principal elements: chondroid, fibrous, and myxoid tissue. It is the least common of the benign cartilaginous bone neoplasms. There is a male predominance, with a male-to-female ratio of 1.5 to 2:1. The tumor tends to occur around the knee joint but can involve any bone. The tumor is usually solid but may contain cystic or hemorrhagic areas. On MR images, signal intensities of this tumor vary with the proportions of chondroid, fibrous, and myxoid tissues present. CT may be better than MRI in delineating matrix calcification and sclerosis around the tumor.¹⁰⁹

Osteoid Osteoma

Osteoid osteomas are relatively common, following only osteochondromas and fibrous cortical defects in prevalence. The male-to-female ratio is 3:1. They typically occur in teenagers and young adults and are rare before 5 and after 30 years of age. These tumors occur most frequently in the femur, tibia, and humerus and involve the diaphysis and, less commonly, the metaphysis. When the spine is involved, the posterior elements are typically affected. The main clinical symptom is pain relieved by aspirin.

CT is very accurate in detecting the nidus and is preferred to MRI for evaluating osteoid osteoma.^{34, 56, 62} Occasionally, an osteoid osteoma can be confused with a stress fracture on MR images because of edema in the bone

marrow. On a CT scan, the typical appearance of an osteoid osteoma is an area of sclerosis surrounding a small (<1 cm) radiolucent nidus (Fig. 46-2). Lesions larger than 1.5 cm are considered osteoblastomas.

The nidus may contain calcifications, the number of which can vary from none to enough to bring about almost complete calcification with only a thin peripheral rim of low density. For full evaluation of the nidus, thin-section CT with 2-mm slices is needed because the nidus is often less than 1 cm in diameter. The nidus enhances on dynamic CT scans, and depending on the degree of calcification, it has low signal intensity on T1-weighted MR images and variable intensity on T2-weighted images.

The surrounding bone marrow has low signal intensity on all pulse sequences in the presence of reactive sclerosis or high signal intensity on the T2-weighted images in the presence of edema (Fig. 46-3).^{20, 28} Osteoid osteomas in younger patients tend to be associated with more extensive peritumoral edema.²⁸ When the osteoid osteoma is interarticular, an associated joint effusion may be detected.⁸⁸

Osteoblastoma

Osteoblastoma is a rare benign tumor. It is at least four times less common than osteoid osteoma. There is a male predominance, with a male-to-female ratio of 2.5:1. Its peak incidence is in the second decade, and it is rare before 10 years of age and after 30 years of age. Its most common location is the spine, usually in the posterior elements. In the long bones, it is most often located in the metadiaphyseal region; in rare circumstances, it can extend into the epiphyses in the adult.

On CT scans, an osteoblastoma appears as an expansile lytic lesion, often with a mineralized matrix, surrounded by a thin bony shell. Dense sclerosis and periosteal reaction may occasionally be present. An osteoblastoma typically has low to intermediate signal intensity on T1-weighted MR images and high signal intensity on T2-weighted images. Edema in the surrounding soft tissues and in the bone marrow beyond the tumor margins is common.^{5, 21, 58, 92}

Nonossifying Fibroma

Nonossifying fibroma and fibrous cortical defects share the same tissue appearance and differ only in size, the

Figure 46-2. Intramedullary osteoid osteoma in a 9-year-old girl with knee pain. **A**, CT scan reveals an area (nidus) of sclerosis with a central lucency in the medullary cavity. **B**, Coronal T1-weighted spin-echo image (TR = 650 msec, TE = 20 msec) demonstrates an area of decreased signal intensity corresponding to the sclerosis seen in **A**; the nidus shows intermediate signal intensity.

Figure 46-3. Osteoid osteoma. *A*, CT scan demonstrates an area (nidus) of sclerosis with a central lucency in the talus. Calcifications are present in the center of the nidus. *B*, Sagittal T1-weighted image shows decreased signal intensity in most of the talus, resulting from bone marrow edema. *C*, Sagittal T2-weighted image demonstrates high signal intensity in the bone marrow as a result of edema. The nidus also shows increased signal and is surrounded by a rim of low signal intensity that corresponds to the sclerosis seen in *A*.

fibrous cortical defects being smaller. They are sometimes called *fibroxanthomas* because they contain spindle-shaped fibroblasts and xanthoma (foam) cells. They are the most common benign lesion of bone and have been reported in 30% of normal children. Most of these non-neoplastic developmental aberrations are asymptomatic and disappear spontaneously. The male-to-female ratio is 1.5:1, and the peak incidence occurs around 10 years of age.

Nonossifying fibromas and fibrous cortical defects are usually localized to the metaphysis of a long bone and are most commonly found about the knee (distal femur and proximal tibia). They are uncommon in the upper extremities. Their radiographic appearance is often pathognomonic, and no additional studies are usually necessary. They are frequently seen as an incidental finding on MRI examinations of the knee and can have a varied MRI appearance (Fig. 46-4).

In the early stages, when the lesion is completely lytic on plain radiographs, it may have high signal intensity on T1-weighted images as a result of an abundance of xan-

thoma cells containing fat. Linear structures of low signal intensity are often present and represent fibrous septa or osseous pseudosepta. When the lesion starts healing, it has low signal intensity on both T1-weighted and T2-weighted images because of increased fibrous collagen, mineralization, and, possibly, hemosiderin deposits.^{47, 84} The lesions are always well defined and are never surrounded by bone marrow edema.⁵⁴

Simple Bone Cyst

The simple bone cyst is a benign cystic lesion of bone of unknown etiology. It arises in the metaphysis of the bone, but with growth it tends to move away from the growth plate toward the diaphysis. It is a common bone lesion, following only nonossifying fibromas and exostoses in prevalence. The male-to-female ratio is 2.5:1. It can be seen in any age group but is very rare before 5 years and after 20 years of age. The most common site is the proximal humerus, followed by the proximal femur. All other locations are rare.

Figure 46-4. Nonossifying fibroma in an 18-year-old woman presenting with knee pain and a possible meniscal tear. *A* and *B*, Sagittal spin-echo image (TR = 550 msec, TE = 17 msec) (*A*) and fast imaging with steady-state precession (FISP) sequence (TR = 30 msec, TE = 13 msec, flip angle = 40 degrees) (*B*) reveal a well-defined lesion with a low-signal-intensity rim. The lesion has the same signal intensity as muscle on the T1-weighted image and increased signal intensity on the more heavily T2-weighted FISP image. *C*, Radiography confirmed the diagnosis of a classic nonossifying fibroma.

Simple cysts are central, lytic, expansile lesions. Their radiographic appearance is usually diagnostic, and neither MRI nor CT is usually necessary. They are well defined and have low signal intensity on T1-weighted images and high signal intensity on T2-weighted images as a result of their fluid content (Fig. 46-5). Typically, they are homogeneous on both T1-weighted and T2-weighted images unless hemorrhage has occurred. Peripheral low-signal-intensity borders represent reactive sclerosis. No edema is present in the surrounding bone marrow or muscle. CT is superior to MRI in detecting subtle infractions of the lesion.

Aneurysmal Bone Cyst

Aneurysmal bone cysts are expansile lytic lesions that contain thin-walled, cystic cavities; their cause is unknown. They can be seen at any age, although 75% are seen in patients younger than 20 years of age and they are rare after 30 years of age. There is a slight female predominance, with a male-to-female ratio of 1:1.5.

Aneurysmal bone cysts can occur in any bone but arise predominantly in the long bones and the spine. In the long bones, they are usually metaphyseal or metadiaphyseal. In the spine, they involve the posterior elements and may extend into the body, but involvement of the vertebral body alone is rare.

On CT scans, the cyst appears as an expansile lesion with a thin cortical shell (Fig. 46-6). Fluid-fluid levels may be seen and are thought to represent sedimentation of degraded blood cell products within the cystic cavity.⁴⁵ Fluid-fluid levels are best visualized if the patient is immobilized for some time before scanning. Fluid-fluid levels are a nonspecific finding and have also been described in giant cell tumors, chondroblastoma, and telangiectatic osteosarcomas.¹⁰⁰

On both T1-weighted and T2-weighted MR images, an aneurysmal bone cyst appears as a well-defined, expansile mass with multiple internal septations, surrounded by a well-defined, low-signal-intensity rim of variable thickness.^{4, 20, 46, 73, 112} The rim represents a bony shell. Fluid-fluid levels are often seen within well-defined cystic cavities.⁴⁶ On T1-weighted images, signal intensity in the cyst may be higher than that of muscle because of intracystic hemorrhage. One cavity may have signal intensity characteristics that are markedly different from those of an adjacent cavity. The different signal characteristics probably reflect intracystic hemorrhage of different ages. Edema may be present in the surrounding muscles. Septations within the lesion enhance after administration of gadolinium diethylenetriamine-penta-acetic acid, or pentetic acid (Gd-DTPA), but the cystic component does not enhance.

Figure 46-5. Simple bone cyst. *A*, Radiograph of a classic simple bone cyst of the humerus. *B*, Coronal T1-weighted spin-echo image (TR = 400 msec, TE = 17 msec) shows a well-defined, low-signal-intensity lesion expanding the humeral shaft. *C*, Axial T2-weighted spin-echo image (TR = 2000 msec, TE = 90 msec) reveals high signal intensity in the lesion, suggesting the presence of fluid.

Giant Cell Tumor

The giant cell tumor is found relatively frequently, but malignant transformation is rare, occurring in fewer than 10% of lesions. There is a slight female preponderance, and the peak incidence is between 20 and 49 years of age. It is rare before closure of the growth plate or after 50 years of age. This tumor is localized to the metaphysis.

Ninety percent of cases involve the long bones, where the lesion is localized to the metaepiphyseal region. More than 50% of giant cell tumors involve the knee (distal femur and proximal tibia metaepiphyseal region). Other bones that can be affected include, in order of frequency, the distal radius, sacrum, distal tibia, proximal humerus, pelvis, and proximal femur. Other sites are rarely affected.²³

On CT scans, giant cell tumors appear as lytic lesions with thinning and erosion of the cortex (Fig. 46-7).²⁶ A sclerotic margin may be present between the tumor and the normal marrow cavity. On MR images, giant cell tumors are well defined with a low-signal-intensity rim or halo surrounding the tumor. On T1-weighted images, they have intermediate signal intensity and are usually homogeneous; on T2-weighted images, they have intermediate to high signal intensity and may be inhomogeneous.^{14, 23, 41, 60, 71}

Focal areas with increased signal intensity may be seen on both T1-weighted and T2-weighted images and represent hemorrhage. Fluid-fluid levels, often seen in aneurysmal bone cysts and telangiectatic osteosarcomas, are present only rarely in giant cell tumors.¹⁰⁰

Both CT and MRI accurately demonstrate the intraosseous and soft tissue extension of the tumor; CT is better at showing cortical destruction, whereas MRI is better at demonstrating intra-articular involvement as a result of its multiplanar capability.⁹⁸

Malignant Skeletal Tumors

Multiple Myeloma

Multiple myeloma is a multifocal malignant proliferation of plasma cells and is the most common primary malignant tumor of the skeleton. There is a male predominance, with a male-to-female ratio of 1.5:1. It is common after age 50 years and is rare before age 30 years. Because this neoplasm derives from bone marrow elements, it involves bones containing red marrow: the skull, ribs, sternum, pelvis, proximal humeral metaphysis, and proximal

Figure 46-6. Aneurysmal bone cyst in a 19-year-old man with knee pain. **A,** Radiograph shows a large expansile lesion of the proximal tibia. **B,** CT scan reveals a large lesion with marked expansion of the tibia and with fluid-fluid levels. **C,** T1-weighted spin-echo image shows a large lesion with fluid-fluid levels.

femoral metaphysis. At the time of diagnosis, it is often disseminated throughout the red marrow of the axial skeleton.

Infiltration of bone marrow has two forms:

1. In the *diffuse* form, myeloma cells are mixed with hematopoietic cells. This form is difficult to image; the only MRI manifestation is an inhomogeneity of the bone marrow signal intensity that is difficult to quantitate and is **subjective**.^{33, 72} CT, plain radiographs, and scintigraphy may result in negative findings.
2. In the *focal* form, normal bone marrow is displaced by nodules composed entirely of myeloma cells. Untreated myelomatous lesions reflect decreased signal intensity on T1-weighted images and increased signal intensity on T2-weighted images when compared with the surrounding bone marrow.^{33, 72} CT demonstrates purely osteolytic lesions in the trabecular bone, which occasionally extend to involve the cortex (Fig. 46-8).⁸⁹ After irradiation, these lesions show low signal intensity on

both T1-weighted and T2-weighted images, and a sclerotic border develops, as seen on CT.

Osteosarcoma

Osteosarcoma is a malignant neoplasm characterized by production of osteoid by the tumor cells. It is the second most common primary malignant tumor of bone after plasmacytoma. It is a rare tumor, representing only 0.2% of all malignant tumors. There is a male predominance, with a male-to-female ratio of 2:1. Its peak incidence is in the second decade, and it is rare before 10 and after 30 years of age.

Osteosarcoma can occur in any bone, but it has a strong predilection for the distal femur, proximal tibia, and proximal humerus. Two thirds of osteosarcomas are localized to the knee or shoulder.

Osteosarcomas can be divided into two categories: (1) *primary* osteosarcomas, which arise de novo, and (2) *secondary* osteosarcomas, which develop in abnormal bones.

Figure 46-7. Giant cell tumor in a 16-year-old girl with knee pain. *A*, CT scan demonstrates a lytic lesion of the distal femur with marked expansion and thinning of the cortex both anteriorly and posteriorly. *B* and *C*, Coronal MR images show a well-defined lesion. The signal intensity is same as that of muscle on the T1-weighted, spin-echo image (TR = 600 msec, TE = 17 msec) (*B*) and higher than that of muscle on the T2-weighted, spin-echo image (TR = 2500 msec, TE = 90 msec) (*C*).

Underlying bone abnormalities include Paget's disease, complications of radiation therapy, multiple enchondromas, multiple osteochondromas, chronic osteomyelitis, fibrous dysplasia, or infarct. Secondary osteosarcomas, rather than primary osteosarcomas, usually affect older people.

MRI is useful for staging the tumor and for follow-up after treatment.^{13, 31, 35, 75, 82, 90, 91, 113} The osteoblastic compo-

nent of the tumor has low signal intensity on all sequences. The nonmineralized component has low signal intensity on T1-weighted images and high signal intensity on T2-weighted images. Bone marrow extension is best seen on T1-weighted images, where the loss of the high signal intensity of normal bone marrow can be appreciated. Soft tissue extension is best seen on T2-weighted images,

Figure 46-8. Multiple myeloma. *A*, Radiograph of the right hip demonstrates a lytic lesion of the superior pubic ramus. *B*, CT scan confirms the presence of a lytic lesion with destruction of the cortex posteriorly. No sclerotic borders are seen.

whereas tumor and muscle may have the same signal intensity on T1-weighted images. CT is better than MRI in demonstrating matrix mineralization but is less accurate in detecting skip lesions and bone marrow and soft tissue extension (Fig. 46-9).

Telangiectatic osteosarcomas contain large, cystic, blood-filled spaces with fluid-fluid levels that may mimic an aneurysmal bone cyst, but these tumors are usually less well defined than aneurysmal bone cysts.¹⁰⁰

In the last two decades, the development of aggressive chemotherapy has significantly improved the survival of patients with osteosarcoma, and imaging studies are being used to evaluate the tumor's response to treatment. CT findings of a positive response to treatment include (1) marked decrease in size or complete disappearance of the soft tissue mass, (2) increased calcification of the mass, (3) improved delineation of the margins, and (4) formation of a peripheral rim of calcification.^{67, 93}

Decreased signal intensity of the nonmineralized mass on T2-weighted MR images is thought to represent fibrosis or sclerosis of the tumor. Persistent high signal intensity may be a result of either nonresponding tumor or necrotic tumor, reactive granulation tissue, or hemorrhage.^{31, 38, 63} Administration of gadolinium cannot help distinguish viable tumor from reactive inflammation, since both enhance, but a lack of enhancement indicates tumor necrosis.⁹¹

Chondrosarcoma

Chondrosarcoma is a malignant chondroid tumor. It is the fourth most common primary malignant bone tumor, after plasmacytoma, osteosarcoma, and Ewing's sarcoma. Its peak incidence is between 30 and 60 years of age.

According to their intraosseous location, chondrosarcomas may be divided into *central* and *peripheral* lesions. Most chondrosarcomas (~75%) are primary and arise de novo, but the remaining 25% are secondary and develop from malignant transformation of a benign lesion, such as an enchondroma or an osteochondroma (rarely a chondroblastoma). Central chondrosarcomas occur both in tubular bones (e.g., femur, proximal humerus, proximal tibia) and in flat bones (e.g., pelvis). Peripheral chondrosarcomas most commonly arise in flat bones (e.g., pelvis, ribs) and in the spine.

It is difficult to differentiate low-grade chondrosarcomas from benign chondroid lesions; however, the presence of pain in the absence of fracture and cortical destruction and the presence of a soft tissue mass are all signs suggestive of malignancy.^{24, 74} On MR images, chondrosarcoma has a characteristic multilobular configuration. The lobules of hyaline cartilage have intermediate signal intensity, similar to that of muscle on T1-weighted images (Fig. 46-10), and homogeneous high signal intensity on T2-weighted images.^{18, 38, 63, 104} The fibrous septa have low signal intensity on both T1-weighted and T2-weighted images, but they enhance after Gd-DTPA administration.^{2, 35} Calcifications are common in low-grade chondrosarcoma and are best seen by conventional radiography and CT. Endosteal scalloping is also best depicted with CT and plain radiography.

Ewing's Sarcoma

Ewing's sarcoma is a malignant neoplasm that is probably of neuroectodermal origin. Among primary malignant

neoplasms of bone, it follows plasmacytoma, osteosarcoma, and chondrosarcoma in frequency. There is a male predominance, with a male-to-female ratio of 2:1. Its peak incidence is in the second decade, with 90% of cases occurring between 5 and 25 years of age.

Ewing's sarcoma may involve any bone but has a predilection for the long bones and pelvis. In the long bones, it is localized to the diaphysis or metaphysis, and until the growth plate is open, it does not extend to the epiphysis.

MRI facilitates staging of Ewing's sarcoma and is better than CT for demonstrating bone marrow and soft tissue involvement.³⁷ MRI signal intensity characteristics of Ewing's sarcoma are not specific and are similar to those of other malignant neoplasms.^{13, 31, 39} The tumor's signal intensity is lower than or equal to that of muscle on T1-weighted images and is higher on T2-weighted images (Fig. 46-11).

MRI and CT are helpful in evaluating response to treatment. If the tumor is sensitive to treatment, it decreases in size, the periosteal reaction matures, and the bone becomes sclerotic.^{31, 42, 61} High signal intensity on T2-weighted images after treatment does not always indicate a poor response, since it may represent necrosis, reactive granulation tissue, or hemorrhage. Enhancement after Gd-DTPA does not aid in distinguishing reactive changes from residual tumor, but the lack of enhancement indicates tumor necrosis.^{31, 42, 61}

Soft Tissue Tumors

CT has been widely used in detection and staging of soft tissue tumors,¹⁰⁶ but MRI is now the modality of choice in evaluation of these tumors because of its intrinsic high soft tissue **contrast**.^{24, 25, 77, 97, 107} MRI offers improved accuracy in detecting and staging soft tissue masses and is more sensitive than CT in regard to the evaluation of these lesions.

On MR images, benign lesions tend to have well-defined margins, have homogeneous signal intensity, do not encase neurovascular bundles, and are not surrounded by peritumoral edema.⁶ Conversely, malignant lesions typically have poorly defined margins, heterogeneous signal intensity, neurovascular bundle encasement, and peritumoral edema.^{7, 8} Unfortunately, a large overlap exists between benign and malignant lesions, and the ability of MRI to differentiate benign from malignant soft tissue masses remains controversial.^{22, 55}

Benign Soft Tissue Tumors

Lipoma

A lipoma is a benign tumor composed of mature adipose tissue. It is the most frequently occurring benign soft tissue tumor and is often asymptomatic. Superficial lipomas predominate in women, whereas deep lipomas are more common in men. The peak incidence of lipomas occurs between 40 and 60 years of age.

Superficial lipomas are usually localized to the subcutaneous tissue of the trunk and proximal extremities. Deep lipomas are usually in the retroperitoneum, chest wall, and deep soft tissue of the hands and feet.

Figure 46-9. Osteosarcoma in the femur of a 14-year-old boy. Radiograph (A) demonstrates a sclerotic lesion in the metaphysis, with medial destruction of the cortex and periosteal reaction. CT images using soft tissue window settings (B) and CT images using bone window settings (C) reveal a sclerotic lesion of the medial aspect of the femur with an associated soft tissue mass and a periosteal reaction. Four MR images were obtained: two axial spin-echo views (TR = 500 msec, TE = 15 msec) (D) and (TR = 2000 msec, TE = 70 msec) (E) and two coronal spin-echo views (TR = 600 msec, TE = 15 msec) (F) and (TR = 2000 msec, TE = 70 msec) (G). The soft tissue component can be more easily visualized with MRI than with CT, but the periosteal reaction and soft tissue calcification are not as evident. An area of low signal intensity is present on both T1-weighted and T2-weighted images; it corresponds to the area of sclerosis seen on the CT scans.

Figure 46-10. Primary grade I chondrosarcoma in a 36-year-old woman. *A*, Radiograph of the knee demonstrates a lesion with a cartilaginous matrix in the distal femur. *B*, CT scan shows the calcifications in the matrix of the lesion. *C* and *D*, Sagittal (*C*) and coronal (*D*) spin-echo images (TR = 500 msec, TE = 17 msec) demonstrate a lobulated lesion in the medullary cavity. The exact extension of the lesion is easily appreciated, but the matrix calcifications are poorly seen.

On CT scans, lipomas have a low attenuation coefficient, equal to that of subcutaneous fat, and they do not enhance after administration of contrast material. On MR images, they have the same signal intensity characteristics as subcutaneous fat on all imaging sequences (Fig. 46-12). On both CT and MR images, lipomas have a homogeneous appearance, although occasional thin fibrous septa can be present.^{16, 57}

Vascular Anomalies

Vascular anomalies include hemangiomas, venous malformations, arteriovenous malformations, arteriovenous fistulas, and mixed lesions. The term *hemangioma* has also been used generically to describe all of these vascular anomalies.³¹ Vascular anomalies are more common in fe-

males. They are usually congenital except for post-traumatic arteriovenous fistulas.

On MR images, hemangiomas have similar signal intensity as muscle with T1 weighting and high signal intensity with T2 weighting. The signal is usually heterogeneous with T2 weighting and may be either homogeneous or inhomogeneous with T1 weighting and may contain variable amounts of fat and vessels within the mass.¹¹¹

Phleboliths are seen as focal areas of low signal intensity on all imaging sequences, but they are better identified on plain radiographs or CT scans (Fig. 46-13). Serpiginous areas of low signal intensity are occasionally seen and represent flow void in larger feeding arteries or draining veins.

On MR images, arteriovenous malformations and arte-

Figure 46-11. Ewing's sarcoma. *A*, CT scan reveals a large mass surrounding the left tibia. The mass reflects a density slightly lower than that of muscle. *B* and *C*, Coronal T1-weighted spin-echo image (TR = 700 msec, TE = 15 msec) (*B*) and axial T1-weighted spin-echo image (TR = 800 msec, TE = 15 msec) (*C*) demonstrate a large mass surrounding the fibula. This mass shows a signal intensity similar to that of muscle on the T1-weighted images in *B* and *C* and high signal intensity on an axial T2-weighted image (TR = 2500 msec, TE = 80 msec) (*D*).

riovenous fistulas have large tortuous vessels with flow void due to rapidly flowing blood. Feeding and draining vessels can be identified as vascular structures, but differentiation of veins and arteries is not always possible.^{19, 69, 80}

Desmoid Tumor

A desmoid tumor is composed of fibroblasts. Histologically, the tumor is benign and does not metastasize, but it is locally aggressive, infiltrates contiguous structures, and tends to recur after resection. Desmoid tumors may occur at any age, but most often they are seen in the third and fourth decades.

On cross-sectional imaging, desmoids have well-defined borders two thirds of the time, but the rest of the time the margins are infiltrative and poorly defined. CT scans obtained without contrast enhancement show variable attenuation relative to muscle. After IV contrast administration, desmoid tumors may or may not enhance. Most are hyperdense or isodense with muscle on contrast-enhanced scans.

Desmoid tumors have a signal intensity lower than that of muscle on T1-weighted MR images, with variable signal

intensity on T2-weighted images (Fig. 46-14).¹⁰¹ They may have an aggressive appearance and be confused with a malignant tumor.^{8, 21} The presence of areas of low signal intensity on both T1-weighted and T2-weighted images, resulting from fibrous tissue, is a clue to the correct diagnosis.^{17, 29}

Intramuscular Myxoma

Intramuscular myxoma is a rare benign tumor that contains myxoid tissue. It occurs in older people between 40 and 70 years of age. Usually, it is solitary and has a slow growth rate. Multiple myxomas have been seen in patients with fibrous dysplasias. The tumor is usually localized in a large muscle of the thigh, shoulder, or hip.

The CT appearance is a well-defined, homogeneous mass with a density lower than that of muscle. The mass typically does not enhance after administration of contrast material. It has low signal intensity on T1-weighted MR images and high signal intensity on T2-weighted images.⁹⁹

Figure 46-12. Intramuscular lipoma in a 58-year-old man. A lesion with an appearance of subcutaneous fat is seen in the vastus medialis on the CT scan (A) and on both T1-weighted (B) and T2-weighted (C) MR images.

Pigmented Villonodular Synovitis

Pigmented villonodular synovitis is a benign proliferative process of the synovial lining of a joint, bursa, or tendon sheath. The cause of this lesion is unknown. Repeated trauma, repeated intra-articular hemorrhage, and inflammation have been suggested.

There are two forms. The *focal* form (also called giant cell tumor of the tendon sheath) is more common and usually involves the tendon sheaths of the hands. The *diffuse* form involves large joints, especially the knee. There is no sex predilection. The peak incidence is between 20 and 40 years of age.

MRI characteristics are typical and often lead to the correct diagnosis. As a result of the deposition of hemosiderin within the tumor, the lesion has areas of low signal

intensity on both T1-weighted and T2-weighted images (Fig. 46-15).^{49, 53} The presence of bone erosion on both sides of the joint also suggests the diagnosis. Joint effusion may be present.

On CT scans, bone erosions have well-defined sclerotic borders. On non-contrast-enhanced scans, the soft tissue component may contain areas of high attenuation; these correspond to deposits of hemosiderin.⁸⁶

Malignant Soft Tissue Sarcoma

Liposarcoma

A liposarcoma is a malignant soft tissue neoplasm that contains cells with lipoblastic or lipocytic differentiation.

Figure 46-13. Hemangioma. A, CT scan shows multiple phleboliths in the forearm within a soft tissue mass. B, T1-weighted image shows the lesion to be isointense with muscle; an area that shows increased signal intensity corresponds to fat interposed between vascular elements. C, T2-weighted image shows vascular elements of high signal intensity. D, Coronal T1-weighted image shows large tortuous vessels with flow void caused by rapidly flowing blood.

Figure 46-14. Desmoid tumor. Axial spin-echo images, T1-weighted axial spin echo (A) (TR = 540 msec, TE = 15 msec) and T2-weighted axial spin echo (B) (TR = 2000 msec, TE = 80 msec) demonstrate a lesion in the subcutaneous tissues of the back. The T1-weighted image (A) shows low signal intensity; the T2-weighted image (B) shows intermediate signal intensity and an area of low signal intensity. The low signal intensity seen on each sequence suggests fibrous tissue and aids in the diagnosis.

Figure 46-15. Pigmented villonodular synovitis. Sagittal spin-echo images (A) (TR = 400 msec, TE = 20 msec) and (B) (TR = 2300 msec, TE = 80 msec) demonstrate a large, low-signal-intensity mass inferior to the patella in the Hoffa fat pad. Low signal intensity is the result of hemosiderin deposits in the tumor.

Figure 46-16. Low-grade liposarcoma. A and B, Coronal spin-echo image (A) (TR = 800 msec, TE = 17 msec) and axial spin-echo image (B) (TR = 800 msec, TE = 17 msec) demonstrate a large mass in the medial compartment of the thigh. A large part of the lesion shows the same signal intensity as fat; in some areas, however, the signal intensity is similar to that of muscle, making it possible to distinguish this lesion from a benign lipoma. C, Axial T2-weighted, spin-echo image (TR = 2500 msec, TE = 90 msec) shows the nonlipomatous portions of the tumor with a signal intensity higher than that of fat.

It is the second most common malignant soft tissue tumor after malignant fibrous histiocytoma. Its peak incidence is between 50 and 60 years of age, and it is rare before 20 years of age. Liposarcomas are most common in the extremities, especially the thigh, and in the retroperitoneum.

Liposarcomas can be divided into four groups on the basis of their histologic characteristics: (1) well-differentiated (2) myxoid, (3) round cell, and (4) pleomorphic.

The CT or MRI appearance depends on the degree of differentiation.^{50,57} The portions of the tumor that contain fat demonstrate a low attenuation coefficient on CT scans and have high signal intensity on T1-weighted MR images. The nonlipomatous portions of the tumor have a higher attenuation coefficient than fat on CT scans; their signal intensity is similar to that of muscle on T1-weighted MR images (Fig. 46-16) and is higher than that of fat on T2-weighted images.⁶⁴

A well-differentiated liposarcoma and an atypical lipoma can share the same characteristics on both CT and MRI, making differentiation between these two entities difficult.¹⁶ More aggressive liposarcomas may contain no fat that is detectable by either CT or MRI (Fig. 46-17). In these cases, the appearance of the tumor is indistinguishable from that of other malignant soft tissue tumors.

Malignant Fibrous Histiocytoma

Malignant fibrous histiocytoma is a tumor that develops from a primitive mesenchymal cell; it has markers of

histiocytoid differentiation. It is the most common malignant neoplasm of soft tissues. It is seen more often in men, with a peak incidence between 50 and 70 years of age. Fifty percent are localized in the lower extremities, 20% in the upper extremities, and 20% in the abdominal cavity and retroperitoneum. Other locations are rare.

On MR images, malignant fibrous histiocytoma has low signal intensity with T1 weighting and heterogeneous high signal intensity with T2 weighting (Fig. 46-18).^{27,66} On CT scans, its density is the same as that of muscle and it frequently contains areas of lower attenuation that correspond to areas of necrosis.⁸⁵ MRI is better than CT in determining extent of tumor, but CT is superior in detecting bone involvement and calcifications within the tumor. Calcifications have been seen in up to 20% of malignant fibrous histiocytomas.²⁷

Synovial Sarcoma

Synovial sarcoma is a malignant soft tissue tumor that develops from undifferentiated mesenchymal cells. It is relatively common, following malignant fibrous histiocytoma, liposarcoma, and rhabdomyosarcoma in prevalence. There is a slight male predilection and a peak incidence between 15 and 35 years of age.

Only 10% of synovial cell sarcomas are within a joint. Usually they are located adherent to a joint capsule, bursa, fascia, or tendon sheath. They are most common in the lower extremity.

Figure 46-17. Well-differentiated liposarcoma. A, CT scan shows a large mass with heterogeneous density, suggesting that portions of this mass are necrotic, but fat density is not identified. B and C, Axial (B) and coronal (C) spin-echo images (TR = 600 msec, TE = 15 msec) show a large mass with heterogeneous signal; small foci with higher signal intensity may represent hemorrhage or fat within the tumor.

Figure 46-18. Malignant fibrous histiocytoma in the medial compartment of the thigh. A and B, Coronal T1-weighted spin-echo image (TR = 600 msec, TE = 15 msec) (A) and axial T1-weighted spin-echo image (TR = 700 msec, TE = 15 msec) (B) reveal a large mass reflecting low signal intensity. C, Axial T2-weighted spin-echo image (TR = 2500 msec, TE = 80 msec) demonstrates that the mass has heterogeneous high signal intensity.

Figure 46-19. Synovial sarcoma. A, Axial proton-density image reveals intermediate to high signal intensity. B, Axial T2-weighted image reflects heterogeneous high signal intensity.

Synovial sarcoma has low to intermediate signal intensity on T1-weighted MR images and heterogeneous high signal intensity on T2-weighted images.^{65, 70} This tumor is often multilocular with internal septation, and occasionally fluid-fluid levels are seen (Fig. 46-19).¹⁰⁰ Calcifications are present in 30% of the cases and are best seen on CT scans.³ The presence of extensive calcification indicates a better prognosis.¹⁰³

Computed Tomography and Magnetic Resonance Imaging of the Foot and Ankle

Ken L. Schreibman

Overview

All imaging of the foot and ankle should begin with conventional radiographs. It is preferable that one obtain radiographs of the foot with the patient standing in order to visualize the bones in their weight-bearing alignment. The standard practice is to obtain anteroposterior (AP) and lateral views.³ The oblique AP projection is a useful additional view, particularly to assess the alignment of the tarsal-metatarsal joints (Fig. 47-1). Ankle radiographs are typically obtained with the patient not bearing weight, and the standard series consists of three views⁴: (1) AP, (2) mortise, and (3) lateral (Fig. 47-2). The mortise view is similar to the AP view, with the leg internally rotated 15 degrees. This projection better profiles the ankle mortise.

Advanced imaging techniques are often employed when (1) radiographs cannot elucidate the cause of the symptoms, (2) better anatomic detail is required, or (3) the pathologic process primarily involves the soft tissues. Computed tomography (CT), magnetic resonance imaging (MRI), radionuclide scanning, and ultrasonography (US) each yield additional diagnostic information. Which advanced imaging study should be used depends on the findings on the initial radiograph and the clinical question being asked (Fig. 47-3).

A discussion of radionuclide scanning and ultrasonography of the foot and ankle, other than the brief reviews presented next, is beyond the scope of this chapter.

Computed Tomography

CT is best employed when the clinical or surgical question involves assessing the integrity of the cortex, particularly along articular surfaces. Most modern CT scanners have the ability to create two-dimensional (2D) reformatted images in any plane. This is particularly useful for examining joints that are difficult to profile radiographically, such as the subtalar joint. In the setting of trauma, CT is often used to reveal the pattern of calcaneal fractures as well as the extent of other intra-articular fractures. CT clearly demonstrates cortical fusion in cases of attempted arthrodesis and cortical irregularity in cases of osteoarthritis. CT is also our imaging modality of choice to evaluate tarsal

coalitions, both solid and nonosseous. Example are demonstrated in the first half of this chapter.

Magnetic Resonance Imaging

MRI is used in most other situations. Soft tissue structures, particularly the ankle tendons, can be displayed with a high degree of anatomic and pathologic detail. The extent of abnormal soft tissue and osseous masses can be shown in multiple planes. MRI is also extremely sensitive in detecting radiographically occult bone lesions and osteochondral defects. Examples are presented in the second half of this chapter.

Nuclear Medicine

With the increasing use of MRI for the imaging of occult lesions of the foot and ankle, the role of nuclear medicine is diminishing in many imaging centers. Bone scans remain useful as a screening modality to detect the presence of bone disease. When one is screening for lesions in both feet or throughout the skeleton, a bone scan may be more practical than MRI. In patients with Charcot's arthropathy and advanced neuropathic deformity, the specificity of a bone scan, combined with a technetium-labeled white blood cell scan, can be higher than for MRI.

Ultrasonography

The role of ultrasound is somewhat limited in evaluation of the foot and ankle. In the hands of a skilled sonographer, ultrasonography can detect ankle tendon pathology. In certain clinical settings, ultrasonography can be helpful in determining the vascular or cystic nature of a soft tissue mass and in detecting nonradiopaque foreign bodies, such as a wooden splinter.

Computed Tomography Technique and Anatomy

With modern CT scanners capable of rapidly acquiring many thin axial slices, the approach toward imaging an

Figure 47-1. Weight-bearing radiographic foot series in an asymptomatic 41-year-old male radiologist. *A*, Anteroposterior radiograph. *B*, Oblique radiograph. *C*, Lateral radiograph. The upward-pointing *white arrow* was placed by the technologist to indicate the patient was standing. The heel spur (*black arrow*) at the origin of the plantar fascia is of doubtful clinical significance in this normal volunteer, who has never had heel pain. *D*, In most radiology departments, the x-ray tube cannot be lowered to the floor. Weight-bearing lateral views can be obtained by having the patient stand on a wooden box. The central x-ray beam (*dashed arrow*) passes through the foot, from lateral to medial, striking the film cassette held upright between the feet.

Figure 47-2. Non-weight-bearing radiographic ankle series in a 37-year-old man with lateral ankle pain following an acute inversion injury. *A*, Anteroposterior radiograph. *B*, Mortise radiograph. *C*, Lateral radiograph. The ankle joint and hindfoot are normal. The region outlined by the *dashed rectangle* in *C* is photographically magnified in *D*. *D*, Close inspection of the base of the fifth metatarsal on the lateral view of the ankle reveals a proximal diaphyseal fracture, a *Jones fracture* (*arrow*). Fractures of the base of the fifth metatarsal often present clinically as lateral ankle pain. The technologist must be careful to include the base of the fifth metatarsal on all lateral views of the ankle.

Figure 47-3. Flow chart for advanced imaging techniques (see text). Fx, fracture; OCD, osteochondritis dissecans.

extremity has evolved. We are no longer limited to thinking of a CT scan as a series of individual images. Instead, the goal should be to obtain a solid volume of data and then create 2D reformatted images in planes optimized to illustrate the anatomic structures in question. When the ankle is being scanned, this solid acquisition volume should extend from above the syndesmosis (the distal tibia-fibula articulation) through the entire calcaneus (Fig. 47-4).

For a CT scan of the ankle, the field of view should be large enough to include the hindfoot (talus and calcaneus), the midfoot (navicular, cuboid, and the three cuneiforms), and at least the proximal bases of all five metatarsals. A scanning field of view between 18 and 22 cm is usually sufficient. Indeed, for many patients, it is possible to scan both ankles simultaneously within a 22-cm field of view, thus allowing a side-by-side comparison of the symptomatic ankle with the normal ankle. This can be helpful for evaluating asymmetry of joints such as the syndesmosis, which can be difficult to measure radiographically (Fig. 47-5).

For a CT scan of the foot, the field of view should be enlarged to encompass the entire forefoot (metatarsals and phalanges) as well as the hindfoot and midfoot.

When one is scanning the foot or ankle as a volume for

Figure 47-4. Acquisition volume for CT of the ankle.

Figure 47-5. Asymmetrically wide syndesmosis on the right (double-headed arrow).

subsequent multiplanar reconstruction, the exact position of the extremity within the scanning gantry is less important than ensuring that the limb is stable and will not move throughout the entire course of the scan. Taking a few extra seconds to check that the patient is comfortable and relaxed ensures that the patient will hold perfectly still during the several minutes it takes to obtain the scout images, prescribe the imaging protocol, and acquire the actual images. One way to help the patient hold still is to tape the two feet together. A cardboard or polystyrene plastic (Styrofoam) box can also be used to help keep the feet stable and provides uniformity in patient positioning (Fig. 47-6). Keeping the feet in the center of the gantry often allows for a "small" scanning field of view to be used.

It is not necessary to have a high-speed multislice scanner to obtain high-quality multiplanar reconstruction images. The key is to make the slices as thin as possible with no gap between the slices while the patient is holding perfectly still. In this chapter, all images were acquired using a single-slice helical scanner with 1-mm-thick collimation and a pitch of 1:1. It typically takes 90 to 120

Figure 47-6. Taping feet together to a box helps the patient hold still.

slices, 1 mm thick, to cover the ankle from above the syndesmosis to below the calcaneus.

CT of the foot and ankle allows for assessment of the congruity of articular surfaces in multiple planes. The choice of which planes to reconstruct depends upon which joints are desired to be seen.

The *direct axial plane* (Fig. 47-7A) is parallel to the plantar surface of the foot. It is the primary plane for assessing the ankle syndesmosis as well as the talonavicular, calcaneocuboid, and navicular-cuneiform joints. When scanning is performed with the patient's toes pointing straight up, the direct axial plane is acquired directly with the gantry straight up and reconstruction in this plane is not necessary. If the patient cannot be placed in this toes-up neutral position, it may be necessary to create reconstruction images in the direct axial plane.

The *oblique axial plane* (Fig. 47-7B) is parallel to the long axis of the metatarsals. It is the primary plane for assessing the tarsal-metatarsal joint and is useful in evaluation of a Lisfranc's fracture. This plane can be acquired directly by tilting the gantry 20 to 30 degrees so that the scanning plane is parallel to the metatarsals. Alternatively, oblique axial images can be reconstructed off a sagittal reference image, as in Figure 47-7B.

The *sagittal plane* divides the medial side of the foot and ankle from the lateral side. It is equivalent to the radiographic lateral projection of the foot and is created by reconstructing off a direct axial reference image (Fig. 47-7C). If the patient's foot was held in internal or external

Figure 47-8. Direct acquisition in the oblique coronal plane. The dotted line indicates the orientation of the subtalar joint (STJ). The gantry is angled away from the patient, in a plane perpendicular to the subtalar joint, as indicated by the double-headed arrow.

rotation at the time of scanning, the reconstruction slices should be angled accordingly. Sagittal images are often a good secondary plane by which to assess the integrity of the ankle and subtalar joints as well as the talonavicular, calcaneocuboid, navicular-cuneiform, and tarsal-metatarsal joints.

Figure 47-7. Reconstruction planes. A, Direct axial plane. B, Oblique axial plane. C, Sagittal plane. D, Mortise coronal plane. E, Oblique coronal plane.

Figure 47-9. Normal anatomy: direct axial plane. A, Above the syndesmosis. B, Image obtained through the syndesmosis (arrows point to the syndesmosis). C, Image obtained through the ankle joint. D, Top of the calcaneus. E, Middle of the calcaneus. F, Bottom of the calcaneus. The *coronal plane* divides anterior from posterior structures and is equivalent to the AP radiographic projection of the ankle. This plane is customarily used to evaluate the ankle and subtalar joints, and the reconstruction planes can be optimized depending on which joint is in question. The ankle mortise can be clearly profiled via the *mortise coronal plane*, obtained by reconstructing off an axial reference image, along a line between the medial and lateral malleoli (Fig. 47-7D). The subtalar joint is best profiled via the *oblique coronal plane*, obtained by reconstructing off a sagittal reference image, perpendicular to the subtalar joint (Fig. 47-7E). When the oblique coronal images are angled correctly, the middle facet of the subtalar joint has a flat horizontal orientation (see Fig. 47-11C).

Oblique coronal images are of particular surgical importance in planning the management of calcaneal fractures. When technical constraints limit the ability to create satisfactory reconstruction images, or when the surgeon insists on it, images can be acquired directly in this coronal plane. As shown in Figure 47-8, the patient flexes the knees and places the feet flat on the scanning table. (This flexed-knee positioning may not be possible if the patient is in a long-leg cast or has other physical limitations.) Scout images are obtained, and the gantry is tipped with the top *away*

from the patient so as to scan in a plane *perpendicular* to the subtalar joint, typically 20 to 30 degrees.

Figures 47-9 through 47-11 depict the anatomy of the tarsal bones and joints in the direct axial, sagittal, and oblique coronal planes, respectively.

Trauma

After conventional radiography, CT is the most useful modality for assessing the bones following trauma. With multiplanar reformatted images, CT clearly demonstrates the alignment of fracture fragments, intra-articular extent, and the presence of intra-articular loose bodies. Although a CT scan of the foot and ankle can certainly be obtained at the time of the acute trauma, in a multitrauma patient it is often prudent to attend to the most urgent clinical and imaging needs immediately and delay scanning the extremity until the patient is more stable and comfortable. The surgeon may elect to wait several days to a week for soft tissue swelling to decrease before repairing an ankle fracture. As such, a preoperative planning CT scan can be performed a day or two before the scheduled surgery.

Although it is not necessary to obtain a preoperative CT

Figure 47-10. Normal anatomy: sagittal plane. A, Lateral parasagittal ankle. B, Midsagittal ankle. C, Medial parasagittal ankle. scan for each fracture of the foot or ankle, often the surgical approach to calcaneal fractures and many talar fractures, as well as complex fractures of the distal tibia, is dictated by the fracture pattern. If the fragments are severely displaced, the surgeon may request a 3D rendering of the CT scan to better visualize how the fragments should be realigned. In most cases, however, the multiplanar 2D reformatted images described earlier are sufficient for preoperative planning.

Calcaneal Fractures

The calcaneus is the most commonly fractured tarsal bone. Injury to this bone represents 60% of all tarsal

fractures and 2% of all fractures.³⁸ The injuries are often disabling because of the slow healing time and symptomatic sequelae.⁴⁰ Calcaneal fractures are typically the result of axial loading, such as may occur when a person is jumping or falling from a height.

The calcaneus tends to fracture in a characteristic pattern. With axial loading, the wedge-shaped lateral process of the talus impacts into the calcaneus at the angle of Gissane. The fracture then propagates inferomedially (Fig. 47-12). Calcaneal fractures almost invariably extend into the posterior facet of the subtalar joint and may involve the sustentaculum tali and middle facet to a varying degree. For this reason, the oblique coronal plane, angled perpen-

Figure 47-12. Relationship of the lateral process of the talus to calcaneal fracture. **A**, Sagittal reformatted image. With axial loading, the wedge-shaped lateral process of the talus (arrow) impacts into the calcaneus at the angle of Gissane. **B**, Oblique coronal reformatted image demonstrates the classic pattern of a calcaneal fracture, extending from the posterior facet of the subtalar joint inferiorly and medially (dotted line).

Figure 47-13. Calcaneal fracture. **A**, Oblique coronal reformatted image reveal the near-complete disruption of the posterior facet of the subtalar joint (*black arrow*); however, this image also shows that the fracture does not extend into the sustentaculum tali (*asterisk*) and that the middle facet of the subtalar joint is maintained (*white arrow*). By scanning through both hindfeet simultaneously, one may include the contralateral normal left subtalar joint for comparison. **B**, Direct axial image obtained through both hindfeet simultaneously demonstrates the severely comminuted fracture of the right calcaneus. There is also a nondisplaced longitudinal fracture through the cuboid (*arrows*).

dicular to the subtalar joint, is the primary imaging plane in assessment of calcaneal fractures. Axial images should also be examined to determine whether the fracture extends into the calcaneocuboid joint or into the cuboid bone itself (Fig. 47-13).

Surgeons prefer to approach calcaneal fractures from the lateral side. This means that the sustentaculum tali and middle facet of the subtalar joint are not directly visualized. As such, surgeons rely on oblique coronal images to assess the integrity of these medial structures and to assess the relative size of the sustentaculum fragment.

Tibial Fractures

The common Weber-type inversion and eversion injuries of the ankle joint, resulting in fractures of the medial and lateral malleoli, typically do not require a CT scan for management decisions. For more complex distal tibial fracture patterns, however, a multiplanar CT scan may aid in surgical planning.

Comminuted (pilon) fractures involve the distal weight-bearing surface of the tibial (plafond). (*Pilon* is the French term for pestle, as in mortar and pestle.) In a pilon fracture, the articular surface of the tibial is shattered into multiple fragments. To acutely restore gross alignment of the ankle joint, the surgeon may choose to place an external fixation device and delay the more definitive internal fixation for several days. Obtaining a good-quality CT scan of the shattered articular surface while the external fixator is in place should not be a technical challenge. The longitudinal portion of the external stabilization rod tends to cause no appreciable beam-hardening streak artifacts to degrade the reconstruction images (Fig. 47-14). The metal brackets that connect the longitudinal rod to the transverse percutaneous pins are relatively dense and tend to cause artifacts. However, these artifacts are invariably proximal and distal to

the fractured articular surface. As such, axial scanning can be limited to bones and joint structures between the levels of the percutaneous pins. Coronal and sagittal images should be reconstructed in planes optimized to show the surgeon the alignment of fragments within and around the ankle joint.

The distal tibial growth plate begins to fuse in the early teenage years, with the medial side fusing earlier than the lateral side. If a child of this age sustains a fracture through the distal tibial epiphysis, the fracture tends to extend through the lateral growth plate. This Salter-Harris type III fracture has been termed the *juvenile Tillaux fracture* and is well demonstrated with images in the coronal plane (Fig. 47-15).

Whereas the Salter-Harris type III fracture of the ankle follows the juvenile Tillaux pattern, a Salter-Harris type IV fracture occurs in a *triplane pattern* (Fig. 47-16). In a triplane fracture, as in the juvenile Tillaux fracture, the epiphyseal fracture occurs in the sagittal plane and the physal fracture occurs in the axial plane. There is also a component of the fracture extending proximal to the growth plate, through the posterior metaphysis, which occurs in the coronal plane.

Arthritis

CT can be useful in assessing cortical integrity in the setting of chronic foot and ankle pain. Although arthritis is typically evaluated with conventional radiographs, the articular changes from osteoarthritis and erosive arthropathies are well shown with multiplanar CT. Particularly when a surgical fusion (arthrodesis) is being planned, the surgeon may wish to see inside the joints (e.g., ankle and subtalar joints), which are difficult to profile radiographically.

Figure 47-14. Pilon fracture. A, Anteroposterior scout image showing an external fixation device. The percutaneous pins are in the tibial diaphysis (above top on image) and in the hindfoot. The *black arrow* indicates the metal bracket that connects the transverse pins to the longitudinal rod, distal to the ankle joint. There is little hardware at the level of the ankle joint (*white arrow*). The *dotted line* indicates the level of axial image (B). B, Direct axial image obtained through a shattered tibial plafond. The *white arrow* indicates the external fixation rod. C, Coronal reconstruction image. Although there is a small amount of beam-hardening artifact at the level of the metal bracket (*arrow*), this artifact is distal to the fractured tibial plafond. D, Sagittal reconstruction.

Figure 47-15. Juvenile Tillaux fracture. A, Direct axial image demonstrates the slightly displaced fracture through the anterolateral portion of the epiphysis (*white arrows*). B, Coronal reconstruction image demonstrates not only the epiphyseal component of the fracture (*white arrows*) but also the slightly disrupted lateral physis (*black arrows*). Because both ankles were scanned simultaneously, the normal left distal tibial growth plate is available for comparison.

Figure 47-16. Triplane fracture. *A*, Coronal reconstruction image. *B*, Sagittal reconstruction images. *White arrows* indicate the epiphyseal fracture in the sagittal plane. *Black arrows* indicate the physeal fracture in the axial plane. *White arrowheads* indicate the metaphyseal fracture in the coronal plane.

The four key features of osteoarthritis—nonuniform joint narrowing, subcortical sclerosis, subcortical cysts (geodes), and osteophyte formation—can all be demonstrated by CT (Fig. 47-17). Not infrequently, tiny intra-articular

bodies accompany the arthritis; these are often radiographically subtle but can be demonstrated by CT. CT is also useful in detecting cortical erosions that may not be apparent on radiographs (Fig. 47-18).

Figure 47-17. Osteoarthritis. *A*, Direct axial image demonstrates nonuniform narrowing of the medial ankle mortise (black arrows). Many geodes are also present (black arrowheads). *B*, Coronal reconstruction image demonstrates nonuniform narrowing (black arrows) and subcortical geodes (black arrowheads) as well as subcortical sclerosis (white arrowheads). *C*, Sagittal reconstruction image demonstrates nonuniform narrowing and subcortical sclerosis (black arrows) and a small anterior osteophyte (white arrow).

Figure 47-18. CT evaluation of a 34-year-old man who presented to the emergency department with acute onset of non-traumatic pain of his left great toe.

A, Oblique radiograph of the left foot. The region within the dashed rectangle is enlarged in B.

B, Close examination of the first metatarsal showed a thin white curved line just outside of the lateral diaphyseal cortex (ellipse). Initially, this was thought to represent a periosteal reaction from the first metatarsal rather than what it truly was: an erosion of the lateral sesamoid. There is also a marginal erosion of the medial first metatarsal head (white arrow).

C, Axial CT section obtained through the sesamoids of the great toes bilaterally demonstrates the lucent left lateral sesamoid (circle).

D, Coronal reconstruction CT image confirms the erosion in the left lateral sesamoid (oval) as well as in the adjacent lateral metatarsal head (black arrow).

E, An axial CT section proximal to C reveals the marginal erosion seen radiographically in the left medial metatarsal head (white arrow) and an erosion in the right second cuneiform (black arrow). This CT section nicely demonstrates that these two erosions both have well-defined, slightly sclerotic margins with sharp overhanging edges, characteristic of gout. Aspiration of the patient's left great toe metatarsophalangeal joint yielded uric acid crystals.

Osseous Fusion

When symptoms persist for months following trauma, CT can be used to determine the degree of fracture healing. Nonunion occurs in talar, navicular, and some distal tibial fractures but is rare following calcaneal fractures. When there is solid osseous fusion across the fracture line, CT may reveal other causes of the symptoms, such as an intra-articular fragment and secondary osteoarthritic changes. With calcaneal fractures in particular, osteoarthritis can develop in the large weight-bearing posterior facet of the subtalar joint if articular surfaces are not anatomically aligned (Fig. 47-19).

Arthrodesis (surgical fusion of a joint) is a common procedure for treating patients with symptomatic osteoarthritis of the ankle or foot. When symptoms persist beyond the expected postoperative recovery period, a CT scan with images obtained or reconstructed perpendicular to the joint in question can be useful to determine the degree, if any,

Figure 47-19. Coronal reconstruction CT image showing the healed right calcaneal fracture (dotted line). There is secondary osteoarthritis at the ankle and subtalar joints. The normal left hindfoot is included for comparison.

Figure 47–20. The patient is a 55-year-old man with persistent hindfoot pain after an attempted subtalar arthrodesis. Lateral radiograph of the ankle (*A*) and oblique radiograph of the foot (*B*) reveal a single lag screw across the subtalar joint. The degree of osseous fusion across the joint is unclear from these radiographic projections. Oblique coronal (*C*) and oblique sagittal (*D*) reconstruction images clearly reveal no solid cortical bridging across the subtalar joint (*white arrows*). Subsequently, the arthrodesis was redone and a second screw was placed across the subtalar joint.

Figure 47–21. The patient is a 72-year-old woman with persistent hindfoot pain after an attempted subtalar arthrodesis with two lag screws. *A*, Harris radiographic axial view of the calcaneus. *B*, Lateral radiograph of the ankle. These two radiographic projections suggest that the subtalar joint is not fused. However, the surgeon was reticent to subject this patient to a second surgical procedure and requested a multiplanar CT scan to evaluate the subtalar joint. *C*, Direct axial CT image. *D*, Sagittal reformatted CT image. *E*, Oblique coronal reformatted CT image. Despite some beam-hardening artifacts between the two screws, all three planes clearly show no solid osseous fusion across the subtalar joint (*white arrows*).

Figure 47-22. Attempted midfoot fusion in a 26-year-old man. *A*, Lateral radiograph demonstrates a dorsal plate with six screws extending across the talonavicular and navicular-cuneiform joints. *B*, Lateral scout projection for the CT scan. With the toes pointing up, the top of the gantry was angled away from the patient and the midfoot was scanned in the oblique axial plane (*white lines*). *C*, Oblique axial CT image. Even scanning through six screws, the streak artifact is minimal. No cortical bridging is seen across the talonavicular joint (*black arrows*). *D*, Oblique axial CT image, a few slices distal to *C*. At this level, the nonunion of the talonavicular joint is clearly demonstrated (*black arrows*). However, there is solid osseous fusion across the medial navicular cuneiform joint (*white arrow*) and partial fusion across the lateral navicular cuneiform joint (*arrowhead*). *E*, Sagittal reformatted CT image confirms the nonunion of the talonavicular joint (*black arrows*).

of osseous fusion across the attempted arthrodesis. The single cannulated lag screws used to fuse the subtalar joint typically cause no appreciable beam-hardening streak artifacts (Fig. 47–20). When more than one screw is present across the joint (Fig. 47–21) or when several small screws are used with a plate (Fig. 47–22), black streaks can occur in between the screws. However, by optimizing the scanning and reconstruction planes, we can still obtain useful information about cortical integrity.

Tarsal Coalitions

A *coalition* is an abnormal osseous, fibrous, or cartilaginous union between bones.⁶⁸ Tarsal coalitions occur in two

characteristic sites: (1) between the anterior process of the calcaneus and the lateral pole of the navicular and (2) across the middle facet of the subtalar joint.

Coalitions result from failure of fetal primitive mesenchyme to segment by cleavage and thus produce the normal peritalar joint complex.³⁹ The reported incidence of tarsal coalition in the general population is less than 1%.^{53, 82} However, before the advent of CT, many tarsal coalitions, particularly coalitions of the subtalar joint, went undiagnosed. The true incidence is probably considerably greater than 1%.⁹² Approximately 60% of calcaneonavicular coalitions and 50% of talocalcaneal coalitions occur bilaterally.⁶⁰

The subtalar joint complex consists of the subtalar joint,

Figure 47–23. Nonosseous calcaneonavicular coalition in a 12-year-old boy. *A*, Lateral radiograph demonstrates a talar beak (arrowhead). *B*, Oblique radiograph shows the abnormal articulation (arrows) between the anterior process of the calcaneus and the lateral pole of the navicular. *C*, Axial CT image obtained through both feet clearly demonstrates the abnormal articulation (arrows) between the anterior process of the calcaneus and the lateral pole of the navicular on the right. Tiny subcortical geodes are present on each side of this abnormal articulation. The left foot has a normal gap between these bones (rectangle). *D*, Sagittal reformatted images through each foot. The image of the right shows the calcaneonavicular coalition (arrows) and the talar beak (arrowhead). The image of the left shows normal gap (rectangle) between calcaneus and navicular.

the calcaneocuboid joint, and the talonavicular joint. These joints function in unison during the gait cycle, and limitation of motion of any one of these joints limits the motion of the other joints.¹⁵ The altered biomechanics across the talonavicular joint can result in a traction spur, or "beak," arising from the neck of the talus (Fig. 47-23A; see also Fig. 47-25A).⁶⁷ Talar beaks occur less frequently with nonosseous coalitions because some subtalar motion remains.²⁰

Calcaneonavicular coalitions can be demonstrated radiographically with an oblique view of the foot (Fig. 47-23B). There is no normal joint between the calcaneus and the navicular. When adjacent cortical surfaces are present between the calcaneus and navicular, this represents a nonosseous coalition. CT shows this abnormal articulation and, less frequently, reveals subcortical geodes on either side of these nonosseous coalitions, indicating early osteoarthritic changes at these abnormal articulations (Fig. 47-24B; see also Fig. 47-23C).

Talocalcaneal coalitions, because they occur across the middle facet of the subtalar joint, are difficult to demonstrate with conventional radiographs. Although a talar beak may be present on the lateral view, the middle facet of the subtalar joint is not reliably profiled on standard radiographic views of the foot or ankle. For this reason, oblique coronal CT images through the hindfoot are invaluable for suspected talocalcaneal coalitions. On a well-angled oblique coronal slice, the middle facet of the subtalar joint should be horizontally oriented with flat and congruent articular surfaces (see Fig. 47-11C). With osseous coalitions, solid ankylosis is present across this joint (Fig. 47-25C). In nonosseous coalitions, the articular surfaces are not smooth and congruous and tend to have an overgrown appearance (Fig. 47-26; see also Fig. 47-25C).

The clinical syndrome of tarsal coalition, described in the 1920s,^{1, 78} consists of pain, reduced or absent subtalar motion, pes planus, and peroneal muscle spasm (i.e., clonus on inversion stress). The exact cause of peroneal spasm is uncertain; however, peroneal muscle tightness is the result

of tarsal coalition and not the cause. Other considerations in the differential diagnosis of peroneal muscle tightness include juvenile rheumatoid arthritis, osteochondral fracture, subtalar joint infection, and neoplasms. Symptoms usually manifest between 12 and 16 years of age and worsen with increasing age. Conservative treatment options include anti-inflammatory medication and a trial of reduced activity, cast immobilization, and molded orthotics. If conservative treatment fails, surgical options include resection of the coalition and arthrodesis if secondary osteoarthritis has developed.

Magnetic Resonance Imaging Technical Issues

During imaging of the ankle or foot with MRI, it is vital to understand the clinical question the scan is being requested to address. No one standardized protocol can answer all possible questions. The scanning sequences employed—indeed, even the selection of which coil to use and how to position the patient—vary, depending on whether the clinical question is integrity of the ankle tendons or ruling out osteomyelitis of the toes. A marker placed over the site of maximal tenderness or near a non-healing ulcer can be helpful to draw the attention of both the technologist acquiring the images and the radiologist interpreting the images. Such a marker needs to be conspicuous on all imaging sequences, including fat-suppressed sequences, and should be placed on the patient in such a way as to not deform the contour of the skin. Although markers are commercially available,^{3, 42} generic capsules containing vitamin E or docusate sodium (Colace) also work well.

For protocol purposes, an MR image of the "foot" needs to be differentiated from that of the "ankle." Typically, an MR image of the ankle is ordered to evaluate the ankle joint, the bones of the hindfoot and midfoot, the ankle tendons, and the surrounding soft tissues. The field

Figure 47-24. Evaluation of a 51-year-old woman for osteoarthritis of the ankle joint. A, Sagittal reconstruction image shows advanced osteoarthritic changes at the ankle joint (black arrows), including narrowing, subcortical sclerosis, and geode formation. An incidental finding is a nonosseous calcaneonavicular coalition (white arrows). B, Axial images obtained through both feet demonstrate bilateral calcaneonavicular coalitions (white arrows). Tiny subcortical geodes are present on each side of these abnormal articulations.

Figure 47-25. The patient is a 29-year-old radiology resident with a long history of bilateral foot pain. The pain had been worse on the right, was exacerbated by athletics, and was improved with custom orthotics. *A*, Lateral radiographs of both feet reveal a talar beak (*arrowhead*). *B*, Oblique radiographs show no calcaneonavicular coalition (*rectangles*). *C*, Coronal oblique reconstruction CT image demonstrates solid osseous coalition across the middle facet of the subtalar joint on the right (*white arrows*). There is also a nonosseous coalition of middle facet (*black arrows*) as manifested by a joint that is abnormally broad with irregular, noncongruent articular surfaces.

Figure 47-26. Nonosseous coalitions of the middle facet of the subtalar joint bilaterally in an 8-year-old girl. The left middle facet has an abnormal vertical orientation (*white arrow*). On the right, the talar-side middle facet has an abnormal rounded cortical surface (*black arrow*).

Figure 47-27. The open top on this knee coil for a Siemens scanner allows the toes to extend through the coil while the ankle/hindfoot is scanned.

of view for an ankle MR image may incidentally include the metatarsal bases, but the phalanges are often excluded. An MR image of the foot, in contrast, should include the metatarsals and phalanges. Indications for MRI of a foot rather than an ankle would include suspected osteomyelitis or occult fracture of the forefoot, sesamoid disorders, and suspected Morton's neuroma.

Typically, when the ankle or foot is being scanned, the patient is positioned supine with the foot resting comfortably in a neutral position within the coil. It is not necessary to have a dedicated ankle coil to obtain high-quality images. Depending on the specific manufacturer's design, it may be possible to position the patient's ankle comfortably within a coil designed for the head or knee. For example, the top of the Siemens knee coil is open, allowing the toes to extend through it (Fig. 47-27). The General Electric foot coil includes a "chimney" that extends the field of view to include the toes (Fig. 47-28). Foam pads should be used to help immobilize the patient's hindfoot within the coil (Fig. 47-29). When it is necessary to scan the toes

Figure 47-28. This dedicated ankle/foot coil for a General Electric scanner includes a chimney-like extension so that the phalanges can be included in the field of view.

Figure 47-29. A foam pad within the coil (white arrow) helps to immobilize the hindfoot being scanned. A second pad next to the coil (black arrow) gives the contralateral foot a place to rest.

and the available coils do not easily accommodate the toes while the patient is supine, the patient can be positioned prone with the foot plantiflexed. The toes can then be centered within a knee coil, possibly even within a wrist coil.

To screen for osseous abnormalities, such as stress fractures or osteomyelitis, a sequence sensitive to bone marrow edema should always be performed. This can be a fat-suppressed, fast-spin-echo, T2-weighted sequence (TR = ~4000 msec, TE = ~102 msec, ETL = 8) or an inversion recovery sequence (TR = ~3600 msec, TE = ~40 msec, IT = ~150 to 160 msec, ETL = 8).^{*} It is often desirable to have T1-weighted images (TR = ~500 msec, TE < 20 msec) to compare with the marrow-sensitive images.

The ankle tendons should be examined with a sequence that yields good contrast differentiation between the tendons and adjacent structures as well as with a sequence that is sensitive to fluid within the tendon sheaths. Both of these objectives can be obtained with a single spin-echo, double-echo sequence, with a TR in the range of 2150 to 2400 msec, the TE for the first echo about 20 msec, and the TE of the second echo about 80 msec. The first-echo proton-density-weighted images can then be compared side by side with second-echo T2-weighted images at the same slice positions.

As with most MR images, the double-echo sequence is acquired using 256 pixels in the frequency direction. When time permits, higher-resolution images can be obtained using more T1-weighted parameters (TR = ~600 msec, TE = ~20 msec) and a 512-pixel matrix.

Figure 47-30 is a side-by-side comparison of a T1-weighted image obtained by a high-resolution 512-pixel matrix, with proton-density-weighted and T2-weighted images obtained by a conventional 256-pixel matrix. The improved resolution is particularly noticeable in examinations of thin linear structures such as retinacular fibers. Such high-resolution T1-weighted images well illustrate

^{*}ETL = echo train length; IT = inversion time; TE = echo time; TR = repetition time.

Figure 47–30. Comparison of T1-weighted, proton-density-weighted, and T2-weighted images at the same axial slice position. *A*, T1-weighted image obtained with a high-resolution 512-pixel matrix. *B*, Proton-density-weighted image obtained with a standard-resolution 256-pixel matrix. *C*, T2-weighted image obtained with a standard-resolution 256-pixel matrix. The marker (m), indicating the point of maximum symptoms, is a generic docusate sodium capsule and is visible on all three sequences. An incidental finding is an intraosseous ganglion (bracket) within the calcaneus.

normal anatomic structures (Figs. 47–31 and 47–32); however, they are rarely needed to determine the integrity of the ankle tendons.

Rectangular Field of View

Although the spin-echo, double-echo sequence yields images with good spatial and contrast resolution, it can take a long time to acquire. The three factors that determine acquisition time are (1) repetition time (TR), (2) the number of excitations (NEX), and (3) the number of phase encodes. Thus, even at a single excitation, acquiring a 256-pixel matrix with a TR of 2400 msec takes 614 seconds (10.24 minutes).

Although many patients can hold still for a 10-minute acquisition, particularly when the ankle is comfortably immobilized in the coil, some patients may not be able to cooperate for such a lengthy scan. Besides, in many imaging centers, scheduling constraints preclude the use of too many 10-minute sequences. In such instances, using a rectangular field of view can cut acquisition time in half, with no loss of resolution.

Figure 47–33A illustrates a typical axial slice through the hindfoot and midfoot using a conventional square field of view, 16 × 16 cm. If the image is mapped into a 256 × 256 pixel matrix, the resolution is 16 cm per 256 pixels = 0.6 mm per pixel.

One way to cut the acquisition time in half is to use half as many pixels in the phase direction (Fig. 47–33B). If we can decrease the number of phase encodes from 256 to 128, the time of acquisition is decreased from 10 to 5 minutes. However, this yields rectangular pixels with a resolution in the phase direction that is now 16 cm per 128 pixels = 1.2 mm per pixel, half the resolution in the frequency direction. Thus, although acquisition time is gained, resolution is sacrificed. This is a common tradeoff with MRI.

A true timesaving can be achieved if we realize that the foot/ankle is more than twice as long in AP length as in mediolateral (ML) width. A 50% rectangular field of view

in the axial plane, measuring 16 cm in the AP direction and 8 cm in the mediolateral direction, covers the ankle and tarsal bones in all but the largest feet (Fig. 47–33C). This rectangular field of view can be divided into 256 pixels in the frequency direction, and 128 pixels in the phase direction. This yields square pixels with a resolution of 0.6 mm per pixel in both the phase and frequency directions (8 cm per 128 pixels = 16 cm per 256 pixels = 0.6 mm per pixel). Using a 50% rectangular field of view allows only 128 phase encodes to be performed, with only 5 minutes of acquisition time necessary, while still maintaining 0.6 mm per pixel resolution in both directions.

Potential problems with the rectangular field of view technique arise from anatomic structures *wrapping* in the phase direction (see Fig. 47–33C). Any structure extending beyond the lateral margin of the image in the phase direction is mapped onto the medial side of the image. This phase-wrapping problem is always present with MRI and can be overcome by using relatively large fields of view or *phase-oversampling* or *no-phase-wrap* techniques. The risk of phase wrapping with a rectangular field of view can be minimized if the technologist graphically prescribes the axial or coronal slices off a midline sagittal image. Some manufacturers include a second localizer on their scanning consoles, and this allows for easy visual determination for potential phase wrapping. Before starting a lengthy acquisition, the technologist should always confirm that the phase and frequency directions have not been inadvertently switched.

Ankle Tendons

The ankle tendons are best appreciated in cross-section in the direct axial plane (see Fig. 47–31). The oblique coronal plane (see Fig. 47–32) is a good secondary plane by which to observe the medial and lateral tendons as they course under the malleoli. Normal tendons should appear uniformly black on all imaging sequences and have a

Figure 47-31. Normal ankle tendons shown on series of high-resolution T1-weighted MR images obtained in the direct axial plane. A, Image obtained through the top of the syndesmosis. B, Image obtained through the top of the medial malleolus. C, One slice below B: this image demonstrates the normal loss of dark signal of the extensor hallucis longus tendon. D, Image obtained through the talonavicular joint demonstrates the posterior tibial tendon inserting into the navicular (N) and the flexor hallucis longus tendon passing under the sustentaculum tali (asterisk). At this level, the extensor digitorum longus is dividing into separate tendon slips. A&N (artery and nerve) points to the dotted circle surrounding the neurovascular bundle that includes the posterior tibial artery and nerve. Ach, Achilles tendon; EDL, extensor digitorum longus tendon; EHL, extensor hallucis longus tendon; AT, anterior tibial tendon; FHL, flexor hallucis longus tendon; PB, peroneus brevis tendon; PL, peroneus longus tendon; PT, posterior tibial tendon; FDL, flexor digitorum longus tendon.

Figure 47-33. A–C, Rectangular field of view (see text). The grid superimposed on the field of view is meant to illustrate pixel shape and does not represent the actual pixel size. The brackets in C illustrate the portion of the medial heel (*black brace*) that has wrapped onto the lateral side of the image (*white brace*).

sharply defined interface between themselves and adjacent fatty soft tissues. Any increased signal within a tendon on a T2-weighted image indicates the presence of pathology, typically an intrasubstance tear. In addition, more than a trace amount of fluid around an ankle tendon is abnormal,

indicating inflammation or some other pathologic process. The *exception* to this is the *flexor hallucis longus*, which may normally contain some fluid in its tendon sheath (Fig. 47-34C).

Typically, 10 tendons cross the ankle joint. These ten-

Figure 47-34. Comparison of T1-weighted, proton-density-weighted, and T2-weighted images at the same axial slice position. A, T1-weighted image obtained with a high-resolution 512-pixel matrix. B, Proton-density-weighted image obtained with a standard-resolution 256-pixel matrix. C, T2-weighted image obtained with a standard-resolution 256-pixel matrix. The *dotted circle* indicates a normal amount of fluid in the flexor hallucis longus tendon sheath. The *dotted square* indicates a slightly abnormal amount of fluid in the posterior tibial tendon sheath.

Figure 47–35. Ankle tendons, drawn on a three-dimensional reconstructed CT image. *A*, Anterior ankle tendons. *Dashed line*, anterior tibial tendon; *black line*, extensor hallucis longus tendon; *white line*, extensor digitorum longus tendon. *B*, Medial ankle tendons. *Dashed line*, posterior tibial tendon; *white line*, flexor digitorum longus tendon; *black line*, flexor hallucis longus tendon. *N*, navicular. Asterisk represents the sustentaculum tali.

dons can be clustered into four groups according to their anatomic locations. From an imaging standpoint, anteriorly are the anterior tibial tendon, the extensor hallucis longus tendon, and the extensor digitorum longus tendon (Fig. 47–35A). Posteriorly are the Achilles tendon and the plantaris tendon. Laterally, the peroneal longus and brevis tendons pass under the lateral malleolus. Medially, the posterior tibial tendon and the flexor digitorum longus tendon pass under the medial malleolus, whereas the flexor hallucis longus tendon passes under the sustentaculum tali (Fig. 47–35B).

Anterior Tendons

The anterior tendons are well visualized in the direct axial plane (see Fig. 47–31). They extend, uncrossed, across the ankle joint and midfoot. The anterior tibial tendon is the most medial of the three anterior tendons. It extends along the medial aspect of the great toe tarsal-metatarsal joint to insert on the plantar aspect of the base of the first metatarsal and the adjacent medial cuneiform bone.

The extensor hallucis longus tendon is the middle of the three anterior tendons, proceeding straight to its insertion at the dorsal base of the great toe distal phalanx. The most lateral of the three anterior ankle tendons is the extensor digitorum longus tendon; at the level of the midfoot, it fans out into four separate tendon slips, which, in turn, proceed along the forefoot to insert at the dorsal bases of second through fifth middle and distal phalanges.^{46, 62}

Although the anterior tibial and extensor digitorum longus tendons can be followed over a series of axial images (see Fig. 47–31), it is common to lose visualization of the extensor hallucis longus tendon as it curves anterior to the midfoot (see Fig. 47–31C). This is due in part to magic-angle effects. It is important not to misinterpret this lack of visualization as a rupture of the extensor hallucis longus tendon, a condition that is exceedingly rare. The lack of edematous signal intensity along the course of the extensor

hallucis longus on T2-weighted images should reassure the radiologist that there is no pathology.

Pathology of the anterior ankle tendons is rare. Indeed, if a patient indicates that the point of maximal tenderness is directly over the anterior tendons, it is prudent to search for other causes for pain, such as an unsuspected stress fracture (Fig. 47–36).

Certainly, ganglion cysts can arise from any synovium-lined structure, including the anterior ankle tendons. Figure 47–37 shows a synovial cyst arising from and partially enveloping the anterior tibial tendon.

The normal anterior tibial tendon serves as a useful internal standard against which to compare the size of the other ankle tendons. The anterior tibial is normally the largest tendon in axial cross-section (except, of course, the Achilles tendon).⁷⁴ Figure 47–38 illustrates a chronically swollen and scarred posterior tibial tendon, with its cross-sectional area greater than that of the normal anterior tibial tendon.

Posterior Tendons

For anatomic purposes, the Achilles and plantaris tendons together make up the posterior group, although for practical purposes the plantaris is seldom clinically relevant. The plantaris tendon can be very tiny and is generally difficult to find on MR images, particularly if a high-resolution matrix is not employed.

There is seldom confusion in interpreting MR images of the Achilles tendon. The Achilles tendon should appear uniformly straight and black on sagittal T1-weighted images (see Fig. 47–36C) and on fluid-sensitive images (see Fig. 47–36D). A normal retrocalcaneal bursa may be present just in front of the Achilles tendon (Fig. 47–36D, dotted circle). The normal retrocalcaneal bursa should measure less than 6 mm superior to inferior, 3 mm medial to lateral, and 2 mm anterior to posterior.⁷³

In the axial plane, the Achilles tendon should appear

Figure 47-36. The patient is a 45-year-old woman with pain over the dorsum of the midfoot. *A* and *B*, Axial proton-density-weighted and T2-weighted images obtained through the marker indicate the point of maximum tenderness (pmt). Although this point is over the anterior ankle tendons, no edematous signal is seen within or around the tendons. *C* and *D*, Sagittal T1-weighted and fat-suppressed T2-weighted images. A portion of the normal anterior tibial tendon (AT) and the normal Achilles tendon (Ach) are seen. The *dotted square* demonstrates the unanticipated finding of a navicular stress fracture. The *dotted circle* is the normal retrocalcaneal bursa.

Figure 47-37. Swelling anterior to ankle joint in a 23-year-old woman. Axial (*A*) and sagittal (*B*) T2-weighted images of a synovial cyst (*dotted rectangle*) arising from and surrounding the anterior tibial tendon. The tendon itself is normal.

Figure 47-38. The patient is a 57-year-old woman with chronic medial ankle pain. **A**, T1-weighted image obtained with a high-resolution 512-pixel matrix. The chronically swollen and scarred posterior tibial tendon (PT) is larger in axial cross section than the normal anterior tibial tendon (AT). **B**, Proton-density-weighted image obtained with a standard-resolution 256-pixel matrix. There is loss of the normal sharp fat-tendon interface around PT. **C**, T2-weighted image obtained with a standard-resolution 256-pixel matrix. The relative lack of fluid in the tendon sheath is indicative of chronic scarring (stenosing tenosynovitis).

flattened in the AP direction. Distally, the ventral margin of the tendon becomes concave, with upturned corners resembling a smile (see Fig. 47-31D).

A complete tear of the Achilles tendon can be detected clinically and is often diagnosed by a skilled trainer or therapist. The patient can usually identify the exact instant in which the Achilles tendon has ruptured, describing the sensation as if "someone kicked me." The classic Achilles tendon rupture occurs with forced dorsiflexion of the planted foot, such as occurs in basketball or other jumping sports. The classic patient is a middle-aged "weekend warrior" who leads a sedentary life and then attempts to participate in sports (perhaps with younger players) without an adequate warm-up. Of all the tendons of the foot and ankle, the Achilles is the only one for which disorders have a male predominance.⁷³ When it is clinically apparent to all that the Achilles tendon is completely ruptured, confirmation with MRI is usually unnecessary.

Partial tears and the degree of healing of prior injuries of the Achilles tendon can be more difficult to assess by physical examination, thus rendering MRI particularly valuable. There are three types of Achilles tears (Fig. 47-39), similar to the pattern initially described in the posterior tibial tendon with CT scans⁶⁸:

Type I. With this partial, intrasubstance tear (Fig. 47-40), the Achilles tendon is abnormally rounded in axial cross-section and T2-weighted images reveal increased internal signal intensity.

Type II. The Achilles tendon is attenuated, with a few remaining intact fibers (Fig. 47-41).

Type III. With this complete tear, no intact fibers can be identified in the sagittal or axial plane (Fig. 47-42). Classically, complete Achilles ruptures occur 3 to 5 cm proximal to the calcaneal insertion site¹⁷ because this is a relatively hypovascular watershed region.⁷³

On occasion, the Achilles tendon ruptures at the muscle-tendon junction. These unusual proximal tears sometimes require that the imaging coil be repositioned around the

lower calf rather than around the ankle so that the torn and retracted proximal end can be visualized (Fig. 47-43).

An Achilles tendon that has undergone internal healing and scar formation from a prior tear tends to retain the thickened fusiform shape similar to that seen in a type I intrasubstance tear. Unlike a recent type I tear, however, a healed Achilles tendon does not contain increased internal signal intensity (Fig. 47-44).

Medial Tendons

The classic mnemonic "Tom, Dick, and Harry" is useful for remembering the order of the medial ankle tendons:

Figure 47-39. Graphic representation of three types of Achilles tendon tears. The graphics above the roman numerals represent the longitudinal appearance of the tendon, such as would be seen on a sagittal image. The graphics below the roman numerals are representations of an axial slice obtained through the tendon, taken at the level of the dashed line.

Figure 47-40. The patient is a 54-year-old woman with a history of rheumatoid arthritis and several months of persistent heel pain. Fat-suppressed T2-weighted images in the sagittal (A) and axial (B) planes reveal a type I partial intrasubstance tear of the Achilles tendon (*dotted rectangle*). An incidental finding is an abnormal amount of fluid in the posterior tibial tendon sheath (*arrowhead*).

Figure 47-41. Type II partial tear of the Achilles tendon in a 74-year-old man. Sagittal (A) and axial (B) spin-echo T2-weighted images show a few intact Achilles fibers (*arrows*) surrounded by fluid.

Figure 47-42. The patient is a 41-year-old woman with a history of renal transplantation and steroid use. She had experienced acute posterior ankle pain 5 days earlier when bending over while gardening. Sagittal T1-weighted (A) and fat-suppressed T2-weighted (B) images reveal a type III complete tear of the Achilles tendon at the “critical zone” (arrows) 2 cm proximal to the calcaneal insertion. An axial T1-weighted image (C) obtained through the tear reveals no intact Achilles fibers (dotted rectangle). Incidentally noted is an intact plantaris tendon (dotted circle).

Figure 47-43. Complete rupture of the Achilles tendon at the muscle-tendon junction in a 52-year-old man. A, Sagittal T1-weighted image with the coil centered on the calcaneus is too low to include the proximal side of the tear. B, Sagittal T1-weighted image with the coil repositioned above the ankle joint now includes the proximal side of the tear. The marker is at the palpable defect.

Figure 47-44. The patient is a 57-year-old woman with an Achilles tendon that has healed with chronic scarring. Axial T1-weighted (A), axial T2-weighted (B), and sagittal T2-weighted (C) images reveal that the distal Achilles is too round and thick but contains no increased signal.

“T” represents the posterior tibial tendon; “D,” the flexor digitorum longus tendon; and “H,” the flexor hallucis longus tendon. By changing the emphasis to “Tom, Dick, ANd Harry,” with AN standing for the posterior tibial artery and nerve, it is easier to remember that the neurovascular bundle runs between the flexor digitorum longus and flexor hallucis longus tendons (see Figs. 47-31 and 47-32).

The posterior tibial tendon runs directly behind and under the medial malleolus, proceeds medial to the talus, and inserts on the medial pole of the navicular (see Fig. 47-31D). At this insertion site is a focal osseous prominence called the *navicular tubercle*. The bulk of the posterior tibial tendon inserts on this navicular tubercle, although smaller slips of tendon pass under the navicular (see Fig. 47-32C) to insert on the plantar aspect of all three cuneiforms as well as on the base of the second through fourth

The flexor digitorum longus tendon runs directly behind the posterior tibial tendon, although the two tendons maintain individual tendon sheaths. The flexor digitorum longus tendon extends plantar to the bones of the midfoot, crossing superficial to the flexor hallucis longus tendon. This crossover point has been called the “master knot of Henry,”⁴¹ and the sheaths of these two flexor tendons communicate at this point. Distally, the flexor digitorum longus divides into separate tendon slips that insert on the plantar bases of the second through fifth distal phalanges.

The flexor hallucis longus muscle is a posterior structure that originates from the lower two thirds of the back of the fibula. The muscle-tendon junction extends distally to the level of the ankle joint, and the proximal end of the tendon passes through a groove along the posterior talus. Whereas the posterior tibial and flexor digitorum longus tendons pass under the medial malleolus, the flexor hallucis longus tendon passes under the sustentaculum tali. The flexor hallucis longus tendon then crosses deep to the flexor digitorum longus tendon and extends under the first metatarsal to insert on the plantar base of the great toe distal phalanx.

Of the three medial ankle tendons, the posterior tibial tendon is the most prone to tear, characteristically along the portion that curves around the medial malleolus. The posterior tibial tendon is relatively hypovascular in this region.⁷¹ This region of the tendon is also susceptible to mechanical wear as the tendon rubs against the medial malleolus (Fig. 47-45). If the surrounding tendon sheath does not provide adequate lubrication, as in stenosing tenosynovitis or rheumatoid pannus formation, this frictional wear is increased. Perhaps because of these longitudinal frictional stresses, the posterior tibial tendon tends to tear with a longitudinal split rather than with the transverse rupture seen in Achilles tendon tears. When imaged in the axial plane, a longitudinal split in the posterior tibial tendon resembles two individual tendons. This longitudinally split posterior tibial tendon, when grouped with the flexor digitorum and hallucis longus tendons, has been called the *four-tendon sign* (Fig. 47-46).

Even when the posterior tibial tendon is intact, the tendon sheath and surrounding soft tissues should be carefully examined. An abnormal amount of fluid in the tendon sheath indicates active tenosynovitis (Fig. 47-47). Dark, fibrous tissue around the tendon suggests chronic scarring and/or stenosing tenosynovitis (Fig. 47-48). Rheumatoid pannus can also be demonstrated by MRI (Fig. 47-49) and should enhance if an intravenous contrast agent is administered. It has been suggested that these types of inflammatory conditions of the tendon sheath can be ameliorated via therapeutic tenography.⁷²

Lateral Tendons

Laterally, the peroneus brevis and longus tendons share a common sheath as they pass under the lateral malleolus. Distal to the lateral malleolus, the tendons are enveloped with individual sheaths. The peroneal brevis tendon extends lateral to the midfoot and inserts on the tuberosity at the lateral base of the fifth metatarsal. The peroneal longus tendon passes through a groove in the plantar surface of the cuboid, crosses under the midfoot deep to the master

Figure 47-45. Graphic representation of posterior tibial tendon wear progressing to a tear.

A, The posterior tibial tendon (*thick black line*) is susceptible to mechanical wear ("lightning bolts") as it rubs back and forth (*double-headed arrow*) between the underlying medial malleolus and the overlying flexor digitorum longus tendon (*thick gray line*).

B, Graphic representation of a partially torn posterior tibial tendon as it might appear if it were laid flat. The tendon is thickened and "butterflied" open, with the gray region representing abnormal internal signal. *Dashed line* represents the location of cross-section for C to E.

C, Cross-sectional image obtained through B. The *gray wedge* represents abnormally increased signal along the inner aspect of the flattened posterior tibial tendon (*black ellipse*).

D, Same level as C, but the tendonopathy (*gray wedges*) now involves the outer and inner surfaces of the posterior tibial tendon.

E, Same level as D, but wedges of tendonopathy have progressed to a longitudinal tear, giving the appearance in cross-section that the posterior tibial tendon is two tendons.

Figure 47-46. This partial longitudinal tear of the posterior tibial tendon in a 39-year-old woman shows the *four-tendon sign*: 1 and 2, torn posterior tibial tendon; 3 and 4, normal flexor digitorum and hallucis longus tendons.

Figure 47-47. The patient is a 46-year-old woman with chronic pain in the distribution of the posterior tibial tendon. A, Axial proton-density-weighted image demonstrates that the posterior tibial tendon is intact and contains no abnormal internal signal. The tendon is slightly larger in cross-section than the anterior tibial tendon, with loss of the normal fat signal around the tendon. B, Axial T2-weighted image at the same level reveals an abnormal amount of fluid in the posterior tibial tendon sheath (*dotted rectangle*), indicating active tenosynovitis.

Figure 47-48. The patient (same as in Fig. 47-38) is a 57-year-old woman with chronic pain in the distribution of the posterior tibial tendon. *A*, Axial T1-weighted image shows abnormal dark signal rather than fat surrounding the posterior tibial tendon (*dotted rectangle*). *B*, Axial proton-density-weighted image at the same level as *A*. *C*, Axial T2-weighted image at the same level as *A* and *B* reveals no fluid surrounding the posterior tibial tendon, indicating that this is chronic scarring (stenosing tenosynovitis).

knot of Henry, and extends medially to insert on the plantar aspect of the medial cuneiform and the base of the first metatarsal, just lateral to the anterior tibial tendon insertion site.

A trick for identifying the peroneal tendons is to think of the lateral malleolus as a race track (Fig. 47-50). The peroneal brevis, being the shortest, hugs the inside turn. The peroneal longus follows the outside of the curve, running posterior and inferior to the brevis.

Unlike the medial ankle tendons, which are normally round or oval in axial cross-section, the peroneal brevis can normally appear flattened as it passes around the lateral malleolus. The presence of increased signal intensity within the substance of the tendon or of fluid in the surrounding sheath aids in the diagnosis of pathology of the peroneal tendons. It is often helpful to examine the peroneal tendons

over multiple slices by using several imaging planes and sequences (Fig. 47-51).

Peritendon Pathology

Tarsal Tunnel Syndrome

The tarsal tunnel in the ankle is analogous to the carpal tunnel in the wrist. Both are spaces confined by the underlying bones and overlying fibrous ligaments through which pass tendons, blood vessels, and nerves. The roof of the tarsal tunnel is the flexor retinaculum, a broad fibrous band extending between the medial malleolus and the medial tubercle of the calcaneus (Fig. 47-52A). These retinacular fibers help to prevent the medial tendons from becoming dislocated and can be identified on high-resolution axial

Figure 47-49. Rheumatoid arthritis and diffuse medial ankle pain in a 51-year-old woman. Axial proton-density-weighted (*A*) and T2-weighted (*B*) images reveal abnormal signal around both the posterior tibial and flexor digitorum longus tendons. However, this signal is not as bright as the normal fluid in the ankle joint (*white arrow*) and represents rheumatoid pannus (*gray arrows*). The patient remained pain-free for 1 year following a therapeutic tenogram.

Figure 47-50. Graphic representation with coronal high-resolution T1-weighted image demonstrates the relationship of the peroneal tendons to the lateral malleolus. PB, peroneal brevis tendon; PL, peroneal longus tendon.

Figure 47-51. The patient is a 62-year-old woman with lateral ankle pain from a partial tear of the peroneal brevis tendon.

A–C, Axial T1-weighted, proton-density-weighted, and T2-weighted images at the level of the syndesmosis reveal an abnormal amount of fluid in the common peroneal tendon sheath (*white dotted rectangle*).

D–F, Axial T1-weighted, proton-density-weighted, and T2-weighted images at the level of the lateral malleolus reveal abnormal signal within the flattened peroneal brevis tendon (*black dotted rectangle*).

Illustration continued on following page

Figure 47-51 Continued. G-I, Coronal T1-weighted, proton-density-weighted, and T2-weighted images reveal abnormal signal within the substance of the peroneal brevis tendon (*dotted squares*). The marker is over the point of maximum tenderness.

J and K, Sagittal fat-suppressed T2-weighted images reveal abnormal fluid in the common peroneal tendon sheath (*white dotted rectangle*) as well as within the peroneal brevis tendon (*black dotted rectangle*).

images (Fig. 47-52B). Because the tarsal tunnel is a relatively tight space, otherwise innocuous volume-occupying lesions, such as synovial cysts, small nerve sheath tumors, focal synovitis, or rarely even varicose veins, can potentially impinge on the posterior tibial nerve (Fig. 47-53).³²

Accessory Navicular Syndrome

The primary insertion site for the posterior tibial tendon is on the medial aspect of the navicular bone. The accessory navicular bone is an often seen normal variant ossicle just medial and proximal to the navicular bone.⁴⁴ If the accessory navicular bone is large enough, the posterior tibial tendon inserts upon it rather than on the navicular bone itself. Patients with this normal variation are typically asymptomatic unless there is a fracture through the normal fibrous synchondrosis between the navicular and accessory navicular bones.⁵¹ MRI is useful in showing the presence of abnormal fluid between the navicular and accessory

navicular bones (Fig. 47-54). A line of fluid indicates an abnormal pseudoarthrosis between these bones.

Os Peroneum Syndrome

The os peroneum is a common sesamoid bone, located within the peroneus longus tendon as it passes under the cuboid. In rare cases, this normal ossicle can become inflamed and painful.⁸⁰ Chronic inflammation can be suspected radiographically if the os peroneum is abnormally sclerotic (Fig. 47-55A), although this finding is subjective. A more objective finding of os peroneum syndrome is edema within and around the small ossicle, best shown with an edema-sensitive MRI sequence targeted to the lesion (Fig. 47-55C).

Ligament Injuries

Inversion injuries are the most common ankle injury and among the most common musculoskeletal complaints

Figure 47-52. Tarsal tunnel. A, Location of the tarsal tunnel (arrow), deep to the flexor retinaculum. (Illustrated by M. Schenk, M.S., C.M.I.) B, Axial high-resolution T1-weighted image shows the medial neurovascular bundle (dotted ellipse) deep to the flexor retinaculum (arrows).

that bring patients to the emergency department. Most ankle sprains occur in 15- to 35-year-olds. It is estimated that on average an individual strains his or her ankle once every decade. These sprains account for 25% to 50% of injuries that occur in volleyball, soccer, and football.¹⁴ Because the medial (deltoid) ligament is strong, osseous avulsions occur medially. The lateral ligamentous complex is the site of ankle ligament sprains. The laterally supporting ligamentous structures are the ankle and the hindfoot ligaments.¹⁰ The anterior group consists of the anterior

talofibular ligament and the calcaneal fibular ligament (lateral collateral ligament). The posterior talofibular is also part of the lateral collateral ligament, although it is injured only rarely.¹⁴

Supporting the hindfoot are the medial fibers of the inferior extensor retinaculum, the cervical ligament, and the interosseous talocalcaneal ligament. Acute ankle injuries typically affect the anterior talofibular ligament; the calcaneal fibular ligament is next most frequently affected. Acute injuries can be divided by grade or strain:

Figure 47-53. The patient is a 48-year-old man with medial pain in the distribution of the posterior tibial nerve. Axial (A) and sagittal (B) T2-weighted images reveal a ganglion (dotted square) within the tarsal tunnel, causing "tarsal tunnel syndrome."

Figure 47-54. The patient is a 59-year-old woman with medial point tenderness. *A*, Axial T1-weighted image demonstrates an accessory navicular bone (a) separate from adjacent navicular (N). The posterior tibial tendon inserts on the accessory navicular (arrowhead). *B*, Axial fat-suppressed T2-weighted image at the same position as *A*. The line of fluid between the accessory navicular and the navicular indicates an abnormal joint between these two bones instead of a solid fibrous synchondrosis.

Grade I is the stretching of and microscopic injury to the ligament.

Grade II is a partial tear.

Grade III is a complete tear.

Whether to treat these acute injuries surgically or conservatively is controversial. However, 10% to 20% of patients with lateral ankle ligament injuries experience chronic symptoms, and the severity of the initial injury does not correlate well with these long-term symptoms.² Most patients with chronic symptoms eventually require surgical intervention.³³

The role of MRI, particularly in acute injuries, is currently unclear. Most MRI abnormalities are incidental or occur in patients with chronic, nonspecific symptoms. The anterior and posterior talofibular ligaments are seen best on axial MR images. The anterior ligament has an oblique course that is more anterior medially. The posterior talofibular ligament is horizontal.³⁰ The anterior ligament does not normally demonstrate internal signal intensity; it is usually half the thickness of the posterior ligament. The posterior ligament on high-resolution images gives the appearance of internal signal intensity secondary to the microanatomy of its fascicles.⁶⁴ The calcaneofibular ligament is best seen on coronal images. When the calcaneofibular ligament is injured, the anterior talofibular ligament is nearly always injured as well.

The anterior tibiofibular ligament is infrequently torn in isolation, but it may be avulsed off the tibia. Injury to this ligament may also demonstrate an osseous avulsion (Fig. 47-56) or, more commonly, joint fluid violation of its

Figure 47-55. The patient is a 60-year-old woman with lateral point tenderness. *A*, Cone-down of a lateral radiograph of the midfoot. The os peroneum (dotted square) is perhaps slightly sclerotic, but this is a relatively subjective finding. *B*, Oblique coronal T1-weighted image demonstrates the os peroneum (black square). *C*, Fat-suppressed T2-weighted image, same position as *B*. Edema is present within and around the os peroneum (white square), indicative of "os peroneum syndrome."

anterior boundary (Fig. 47-57). In acute ligament sprains, edema is seen in the adjacent subcutaneous fat. The ligament, when injured, may demonstrate internal signal intensity on any imaging sequence. The ligament may also appear widened with irregular margins. With chronic instability, the ligament may become scarred and thick and either demonstrate unusually low signal intensity on T2-weighted images or appear wavy.

The inferior extensor retinaculum inserts into the lateral aspect of sinus tarsi, where it is best seen on lateral sagittal images. The cervical ligament lies in the anterior sinus tarsi, extending from a tubercle on the inferior lateral talar neck to the dorsal calcaneus. It may be seen on coronal or sagittal MR images. The interosseous talocalcaneal ligament, seen just posterior to the cervical ligament, is a thicker band. Injuries to the lateral ligaments may therefore cause abnormally high signal intensity within the sinus tarsi.

The MRI differential diagnosis for this appearance is sinus tarsi syndrome, which may cause a similar appearance of high signal intensity. In sinus tarsi syndrome,

Figure 47-56. Axial CT image of the lower leg demonstrates disruption of the distal tibia fibular articulation with the fibular subluxated anteriorly out of its sulcus (*large arrow*). A large avulsion fragment is seen at the tibial insertion of the anterior tibiofibular ligament (*small arrow*). This avulsion represents an adult Tillaux fracture.

Figure 47-57. On an axial T2-weighted image, the posterior aspect of articular fluid is well marginated by the posterior talofibular ligament (*long arrow*). The fluid extends too far anteriorly with an irregular margin secondary to a tear of the anterior talofibular ligament (*short arrows*).

however, the morphologic integrity of the hindfoot ligaments is intact. Sinus tarsi syndrome may occur idiopathically, following ankle sprains, or in patients with rheumatoid arthritis or gout.

One additional complication, the anterolateral ankle impingement syndrome, may occur as a sequela of ankle sprain. In this syndrome, hypertrophic synovium develops in the lateral talofibular sulcus.⁷ On MR images, the lateral aspect of the joint on axial image, particularly posterior to the anterior talofibular ligament, fills in, with pannus displacing fluid posteriorly.

Stress Reactions

Edema-sensitive inversion recovery and fat-suppressed T2-weighted images are extremely sensitive for the detection of bone marrow pathology, and such a sequence should be incorporated into every MRI study of the ankle or foot. When bone marrow edema is detected in one plane, typically the sagittal plane, it may be desirable to run a second edema-sensitive sequence in a secondary plane, such as the oblique axial plane (Fig. 47-58).

The term *stress fracture* can refer to any scenario in which a bone is subjected to excessive force of such a degree as to cause bone marrow edema but not a frank breach in the cortex. Stress fractures can be caused by excessive or repetitive forces on a normal bone or by relatively normal forces on an abnormally weakened bone. Stress fractures caused by repetitive abnormal forces are perhaps better termed *fatigue fractures*. Such fatigue fractures have been reported in characteristic locations, including the tibiae of runners and the second metatarsals of military recruits (*march fracture*). Fractures caused by relatively minor stresses on bones with preexisting abnormalities are known as *insufficiency fractures* and are common in patients with underlying osteoporosis.

Stress fractures of the tarsal bones can be radiographically occult⁸⁸ but are quite conspicuous when an edema-sensitive MRI sequence is employed (Figs. 47-59 and 47-60; see also Fig. 47-58). The differential diagnosis for bone marrow edema includes not only stress fracture but also arthritic changes, bone bruises, osteomyelitis, and rarely even neoplasms. These conditions can have somewhat similar appearances by MRI, and often the specific diagnosis is based not only on the imaging findings but also on the clinical history.

Plantar fasciitis is a stress reaction occurring at the origin of the plantar aponeurosis from the calcaneus, typically at the medial calcaneal tubercle. Degenerative changes from repetitive microtrauma in the origin of the plantar fascia cause traction periostitis and microtears, resulting in pain and inflammation.⁶⁹ Plantar fasciitis is the most common cause of pain in the inferior aspect of the heel,⁷⁷ and the diagnosis is typically confirmed by clinical symptoms and physical examination revealing tenderness along the medial calcaneal tuberosity. The relationship between plantar fasciitis and heel spurs has never been firmly established. A study of 90 heels in 45 patients found that although 75% of the painful heels had spurs, 63% of the painless heels also had spurs.⁹¹

Most patients with plantar fasciitis respond to conserva-

Figure 47-58. The patient (same as in Fig. 47-36) is a 45-year-old woman with pain over the dorsum of the midfoot. **A**, Sagittal fat-suppressed T2-weighted image. There is bone marrow edema within the navicular (*white rectangle*). This stress fracture of the navicular corresponds to the point of maximal tenderness (*pmt*), as indicated by the capsule on the skin. The *dashed line* indicates the location of the oblique axial slice in **B**. **B**, Oblique axial fat-suppressed T2-weighted image. This secondary plane helps confirm the bone marrow edema within the navicular (*white rectangle*).

tive treatments that include calf stretching, orthoses, non-steroidal anti-inflammatory medication, and occasionally casting. Patients with atypical clinical presentations or who do not respond to conservative therapies may benefit from MRI to determine whether the pain is indeed related to the plantar fascia or to some other cause, such as a tarsal stress fracture. MRI scanning of plantar fasciitis reveals edema around the origin of the aponeurosis. The plantar fascia itself may be abnormally thickened, and edema may be

present in the underlying calcaneal bone marrow (Fig. 47-61).

Osteochondritis Dissecans

Osteochondritis dissecans (OCD) is a common disorder that may affect the femur, capitellum, or talus. It is more common in adolescents and young adults and usually affects men. *Osteochondral lesion or injury* is a better term for this disorder, with OCD best reserved for characteristic lesions in younger patients.

Although fracture was initially thought to be a *sequela* of bone necrosis, most authors now believe it to be the *cause* of this disorder, with necrosis the result. Talar OCD accounts for 1% of all fractures of the talus and 4% of all cases of OCD. OCD of talus, however, occurs in 6.5% of all ankle sprains.⁷⁵ OCD in locations in the foot and ankle other than the talus is exceedingly rare. The cause of this injury is a shear, rotatory, or even compressive (particularly medial talar OCD) force.

When the injury occurs early in life, the cartilage is resilient and it transmits the vector to the underlying bone. Because the bone is less elastic than cartilage is, the bone may fracture without a chondral fracture. However, shear injuries may displace cartilage even in young patients. With aging, cartilage elasticity is decreased; this leads to transchondral and osseous fractures at the time of injury. Even when the cartilage is not fractured, it is still traumatized, leading to premature degeneration.

Healing of OCD results from ingrowth of capillaries across a reduced immobile fragment. Any motion at the fracture site shears off the capillary buds.¹¹ Healing of this lesion thus depends on both the osseous stability of the fragment and the degree of intactness of the overlying cartilage because both of these factors affect the degree of immobilization. The imaging stage of the lesion, therefore, is the main determinant of prognosis.⁶⁵

Figure 47-59. Sagittal fat-suppressed T2-weighted image with a stress fracture of the talar neck (*white rectangle*). Incidentally noted is edema of the superficial soft tissues of the dorsum of the foot (*arrows*).

Figure 47–60. This stress fracture of the cuboid (*dotted squares*) is relatively subtle on the T1-weighted images obtained in the sagittal (*A*) and oblique axial (*B*) planes. On the more edema-sensitive, fat-suppressed T2-weighted images (*C* and *D*), the bone marrow pathologic process is quite conspicuous (*white squares*).

Osteoarthritis occurs in up to 20% of patients with OCD but in up to 75% of patients with *loose* OCD. Loose fragments are surrounded by a high-signal-intensity interface around the fragment on T2-weighted or short tau inversion recovery (STIR) images. Any lesion with an underlying cyst is also invariably loose.⁵⁶ Irregular high signal intensity or incompletely circumferential high signal intensity is consistent with a partially loose fragment.²⁴ The fragment itself is of variable signal intensity; this fragment signal intensity is of no clinical significance. MRI can also be used to assess the intactness of the overlying cartilage with high-resolution techniques.²⁵ The cartilage may be fractured initially, may subsequently become fractured, or

may become degenerated subsequently. The subset of OCD with an overlying cartilage defect is termed *loose in situ* (Fig. 47–62).

Most osteochondral lesions appear to be secondary to chronic stress rather than occurring as a single episode. The lateral talar OCD, however, is usually the sequela of a specific injury and is less frequently stable than medial talar OCD. Medial OCD, which is slightly more common, usually has cup-in-a-hole appearance, with lateral OCD more often seen as a horizontally oriented “wafer.” Medial talar OCD, compared with lateral OCD, is also usually posterior. Anteromedial OCD-like lesions in the talus usually represent subchondral cysts (*geodes*) from osteoarthritis.

Figure 47-61. The patient is a 52-year-old woman with chronic bilateral heel pain.

A, Sagittal T1-weighted image obtained through the left hindfoot reveals thickening of the plantar fascia (arrows).

B, The corresponding sagittal inversion recovery-weighted image reveals edema (arrowhead) deep to the plantar fascia (arrow). Dashed line represents the position of coronal slice (C).

C, Coronal fat-suppressed T2-weighted image demonstrates bone marrow edema (arrowheads) deep to the origin of the plantar fascia (arrow). med, medial side of image; lat, lateral side of image.

D, Sagittal T1-weighted image of the contralateral right foot. The calcaneal bone marrow edema is less conspicuous than it is on more fluid-sensitive sequences.

E, Sagittal inversion recovery-weighted image corresponding to D reveals extensive bone marrow edema along the plantar portion of the calcaneus (arrowheads). Dashed line represents the position of coronal slice (F).

F, Coronal fat-suppressed T2-weighted image shows the bone marrow edema (arrowhead) radiating from the medial-plantar surface of the calcaneus.

Infection

Infection of the foot is common. Approximately 50% of all cases of cellulitis involve the lower extremity. Older patients are often affected because of risk factors such as venous disease, soft tissue edema, and decreased lymphatic drainage. Ulcers are seen in older patients, particularly in those who have diabetes. The rarer necrotizing infection that spares muscle is seen in younger patients.

Soft tissue infection, particularly in diabetes, may be

indolent and can lead to abscesses. These abscesses usually involve the central compartment of the foot spreading along the flexor tendon sheaths. When the soft tissue infection spreads to bone, it usually involves the calcaneus, metatarsals, or talus.⁹⁴ Osteomyelitis that is spread hematogenously is rare in the foot, except in children. In diabetic patients, a complex interplay of infection, infarction, and sensory neuropathic conditions may result in a “neuropathic arthropathy.”⁹⁶ The Lisfranc joint is most commonly affected, followed by the metatarsophalangeal and subtalar joints.

Figure 47-62. On this T2-weighted coronal image, an osteochondral defect is seen medially. The fragment is isointense to adjacent marrow, and no high signal rim is seen around it (*black arrow*). Therefore, there is no definite evidence of loosening. Disruption of the articular cartilage (*open arrow*) is noted; the fragment is thus considered loose in situ.

Cellulitis, as seen with MRI, is manifested by subcutaneous and, less frequently, by deep muscle edema without mass effect. Diffuse high signal intensity on T2-weighted image, common in diabetic patients, typically affects the plantar soft tissue and muscles deep to the plantar aponeurosis. Soft tissue fluid collections, with or without enhancement after gadolinium administration, are also common in diabetic patients.^{9, 58} These collections are typically, but not necessarily, seen near tissue ulcerations.

Osteomyelitis, as seen on MR images, is usually manifested by low signal intensity within the marrow on T1-weighted sequences and commonly by significantly increased intensity on T2-weighted sequences, particularly with fat suppression^{55, 57, 87, 90} (Fig. 47-63). On STIR images, infection also shows high signal intensity, although false-positive STIR images may infrequently occur as a sympathetic response in cases of septic arthritis and in neuropathic disease (Fig. 47-64).²⁸ Intravenous gadolinium may be useful in complicated cases when marrow and soft tissue enhancement may help to differentiate postoperative and neuropathic changes from infection.⁵⁹ Neuroarthropathy may produce collapse of the midfoot. Neuropathic disease can show low signal intensity on most imaging sequences. More often, however, increased signal intensity is seen on T2-weighted images, even without infection.^{37, 79} Variable enhancement with a contrast agent, however, is usually seen. Fluid in tendon sheaths is quite common in diabetes and is rarely of clinical significance; however, when tendon sheath enhancement is seen with gadolinium administration, soft tissue infection is almost always present.

Soft Tissue Masses

Benign soft tissue lesions commonly seen about the ankle and foot include ganglion cyst, lipomas, fibromatosis,

Figure 47-63. On a T1-weighted image (A), low signal intensity is seen within the marrow of the second ray (*curved arrow*). Adjacent soft tissue mass edema is seen (*straight arrow*). The marrow increases in intensity on T2-weighted (fast spin-echo) images (B) (*arrow*) and enhances after gadolinium administration (C); this is consistent with osteomyelitis. Extensive soft tissue enhancement is also seen (*arrows*).

Figure 47-64. Extensive subcutaneous edema with a predominantly plantar distribution (*white arrows*) is seen in a patient with neuropathic disease. Sagittal short tau inversion recovery (STIR) image demonstrates high signal in the navicular and medial cuneiform (*black arrows*).

giant cell tumor or tendon sheath, hemangiomas, and neural tumors, e.g., neurofibroma, schwannoma, and Morton neuroma. The most common malignant soft tissue masses of the foot and ankle are synovial cell sarcoma and malignant fibrous histiocytoma (MFH). Synovial cell sarcomas are most common in teenagers and young adults, whereas MFH is most commonly seen in patients aged 40 years and older. Malignant peripheral nerve sheath tumors, clear cell sarcomas, and liposarcomas are seen less often.

Location is helpful in evaluation of lesions of the foot.

Dorsally, most are ganglions or giant cell tumors of tendon sheath. In the nail bed, fibromas, glomus tumors, and pyogenic granulomas are most common. In the plantar aspect of the foot, they are usually fibromas, giant cell tumors of the tendon sheath, lipomas, or epidermal inclusion cysts. In the tarsal tunnel, neural tumors and ganglions are the most numerous.

MRI is much more useful than CT in the workup and surgical planning for soft tissue tumors. On CT, most tumors demonstrate soft tissue attenuation similar to that of muscle.²³ The peritumoral edema is difficult to distinguish from tumor on CT scans, and this limits detailed preoperative localization.³⁶ CT remains ideal for evaluation of soft tissue calcifications.

MRI is a significant advance over CT in revealing soft tissue tumors, and it offers more precise anatomic localization and potentially improved preoperative diagnoses.^{23, 36} Most tumors, however, do not have specific signal characteristics.⁴⁹ Most tumors are characterized by low signal intensity on T1-weighted sequences and by increased signal intensity on T2-weighted sequences. Lipomas, however, demonstrate high T1-weighted and intermediate T2-weighted signal intensities, similar to the case of subcutaneous fat.⁵⁰ Other tumors that contain fat include liposarcomas and hemangiomas.^{16, 19} Other causes of high signal intensity on a T1-weighted image include hemorrhage in aggressive necrotic tumors such as malignant fibrous histiocytomas or synovial cell sarcomas. Fibrous tumors such as aggressive fibromatosis,^{48, 66} plantar fibromatosis, and some neurofibromas (only centrally⁸³) demonstrate decreased signal on all sequences (except STIR in fibromatosis).

Schwannomas are identified in the region of a peripheral, but not a cutaneous, nerve. These tumors have high signal intensity on T2-weighted sequences, often with a central area of lower signal intensity. Fibromas (Fig. 47-

Figure 47-65. Plantar fibroma in a 44-year-old man. A, Coronal T1-weighted image. B, Coronal proton-density-weighted image. C, Coronal T2-weighted image. The large lesion (*arrows*) is of low signal intensity on all imaging sequences and is confined to the fat of the plantar heel pad.

65) have variable signal characteristics but are seen within the plantar fat adjacent to the aponeurosis, usually close to the calcaneus.^{48, 66} Morton's neuromas are usually of low signal intensity on most imaging sequences²⁹ and can be quite subtle on the MR image (Fig. 47–66). Power Doppler ultrasound has been suggested as a sensitive imaging modality for Morton's neuromas.⁴⁷

Pigmented villonodular synovitis shows areas of decreased signal intensity on both T1-weighted and T2-weighted images, secondary to hemosiderin deposition.^{43, 81} A similar appearance may be seen with giant cell tumor of tendon sheath (Fig. 47–67), rheumatoid arthritis nodules (see Fig. 47–49), and fibromatosis.^{5, 76}

Synovial cysts and ganglion cysts demonstrate fluid characteristics.^{7, 31, 84} They are localized adjacent to joints, and ganglia are septate and have a connection to the joint. Because of the proteinaceous fluid they contain, they are isointense to muscle on T1-weighted images. The appearance of a synovial sarcoma may be remarkably similar to that of a simple synovial cyst, although a portion of its margin is often slightly irregular. Synovial cell sarcomas tend to have more aggressive growth patterns, and they can grow along a tendon sheath.¹² Single-intensity patterns are often heterogeneous on T1- and T2-weighted images, due to hemorrhage and calcification within the mass.

Hemangiomas have heterogeneous signal intensity on T1- and T2-weighted images owing to vascular channels and their signal voids, with areas of fat contained within the lesion. These tumors appear septate or lobulated and have infiltrative margins that routinely violate anatomic barriers. Calcifications in tumors are visualized as regions of signal void and may be difficult to distinguish from flow

voids in highly vascular tumors or from hemosiderin in necrotic tumors. Distinguishing tumor from surrounding edema may be difficult. Typically, the most prominent edema in soft tissue tumors is seen with malignant fibrous histiocytoma, which typically tracks up and down as a single muscle.⁵⁴ Either on STIR images or immediately following contrast administration, the tumor and its pseudocapsule can usually be distinguished from the edema.

The MRI appearance of a soft tumor is often nonspecific for evaluating its aggressiveness. Benign tumors tend to have smooth margins and relatively homogeneous signal intensity on MR imaging and often lack neurovascular and osseous involvement. However, these findings are nonspecific and can also be seen in aggressive malignant neoplasms such as synovial cell sarcoma. Malignant soft tissue tumors tend to be larger lesions that have infiltrative margins and heterogeneous signal intensity on MR imaging in addition to their rapid growth and neurovascular invasion. However, a benign lesion, such as aggressive fibromatosis, can also demonstrate these imaging characteristics. If the MR imaging appearance of a mass does not meet the specific criteria of a simple lipoma, synovial cyst, or hemangioma, biopsy should be performed.

Bone Tumors

Osseous tumors are much less common than soft tissue tumors of the foot and ankle. Osseous tumors continue to be initially evaluated by plain radiography. MRI, however, is useful in localizing tumors and in staging their extent. Most tumors have nonspecific signal characteristics. MRI is thus unable to render a specific preoperative diagnosis; however, signal characteristics may help narrow the differential diagnosis. The role of CT is limited to the evaluation of the degree of cortical involvement.

Primary bone tumors of the feet are rare, accounting for only 4% of all bone tumors and only 3% of resected foot malignancies. The staging system is based on both histologic grade (I = low; II = high; III = metastatic) and whether the tumor is intracompartmental or extracompartmental.²⁷

In the foot, most bone neoplasms are primary. Benign bone neoplasms are more common than malignant ones. The most common benign tumors are enchondromas and osteoid osteomas. The most common primary malignant tumors are chondrosarcomas and Paget's sarcoma. Metastatic tumors are rare and usually occur as a result of colorectal, renal, or bladder primary tumors. Certain bone tumors have a propensity for a specific anatomic location in the feet. The calcaneus is the most common site of aneurysmal bone cysts and chondrosarcomas (Fig. 47–68). In the anterior calcaneus, intraosseous lipomas and unicameral bone cysts are most common. Chondromyxoid fibroma and fibrous dysplasia occur frequently in metatarsals. The talus is the usual location for osteoid osteoma and osteoblastoma. Enchondromas occur in the proximal and middle phalanges and metatarsals.

Osteosarcomas demonstrate low signal intensity on T1-weighted and high signal intensity on T2-weighted sequences.^{34, 86} Matrix calcifications may be seen as areas of signal void. Cortical breakthrough, adjacent soft tissue

Figure 47–66. Morton's neuroma in a 51-year-old man. *A*, Coronal T1-weighted image. *B*, Coronal proton-density-weighted image. *C*, Coronal T2-weighted image. The small, inconspicuous lesion (arrows) between the third and fourth metatarsal heads is of low signal intensity on all imaging sequences.

Figure 47-67. Giant cell tumor of the tendon sheath in a 19-year-old man. *A*, Axial T1-weighted image. *B*, Axial proton-density-weighted image. *C*, Axial T2-weighted image. The soft tissue mass adjacent to the posterior tibial tendon is relatively dark on the T1-weighted and T2-weighted images owing to the presence of hemosiderin. The mass is growing through the torn tendon sheath (arrows). *D*, Axial precontrast fat-suppressed T1-weighted image. Some signal within the mass is brighter than the surrounding suppressed fat, suggesting the presence of proteinaceous fluid or methemoglobin. *E*, Axial postcontrast fat-suppressed, T1-weighted image demonstrates heterogeneous enhancement, indicative of the vascularity of such synovial proliferation.

Figure 47-68. Chondrosarcoma arising from a calcaneal tuberosity in a 30-year-old woman. *A*, Lateral radiograph. The patient complained of heel pain for 10 months until the sclerosis within the calcaneus was recognized. *B*, Sagittal T1-weighted image shows diffusely decreased signal within the calcaneus corresponding to the radiographic sclerosis. *C*, Sagittal fat-suppressed T2-weighted image reveals marrow edema only at the periphery of the sclerotic region. Extensive bright signal, however, is present in the soft tissues immediately plantar to the calcaneus. *D*, Sagittal postcontrast fat-suppressed T1-weighted image demonstrates enhancement only at the periphery of the osseous and soft tissue masses. This enhancement pattern is a result of the relative hypovascularity of chondrosarcomas.

extension, and peritumoral edema may be noted. The signal characteristics are variable and may be affected by the tumor subtype. For example, telangiectatic osteosarcomas may show areas of increased signal intensity on both T1-weighted and T2-weighted sequences. Fluid levels may also be noted in telangiectatic osteosarcomas, but this is a nonspecific finding.⁸⁹ Osteoid osteomas show high signal intensity on T2-weighted sequences. The nidus may be visualized as an area of decreased signal intensity (Fig. 47–69).^{35, 93} Intravenous gadolinium may aid in identifying the nidus, which significantly enhances. Extensive edema surrounding this tumor is also seen both in the marrow and in the adjacent musculature.²² This extensive edema may also be seen in chondroblastomas (Fig. 47–70) and, less frequently and intensely, in osteoblastomas, eosinophilic granulomas, and aneurysmal bone cysts.

Usually, fibrous dysplasia demonstrates decreased signal intensity on T2-weighted sequences.⁶³ However, frequent islands of cartilage and cystic areas may be seen demonstrating increased T2 signal intensity. Nonossifying fibromas are cortically based lesions with decreased T2 signal intensity. A low-signal-intensity rim is seen with healing and increases in thickness with time. Occasional nonossifying fibromas demonstrate increased signal intensity on T2-weighted images.

Hyaline cartilage tumors, such as enchondromas, osteochondromas, and chondrosarcomas, show a lobulated high

signal intensity on T2-weighted sequences.¹⁸ Nonhyaline cartilage tumors, such as chondroblastomas, can show areas of decreased signal intensity on T2-weighted images, although there is a significant amount of overlap.⁵²

Aneurysmal bone cysts demonstrate septations and fluid-fluid levels. The cystic areas may show varying signal intensity, depending on the stage of blood breakdown. Small diverticulum-type outpouchings have been described. A well-defined low-signal-intensity rim may also be noted. Internal high signal intensity on T1-weighted images is characteristic, as is susceptibility artifact on gradient-echo images.^{21, 61}

Intraosseous lipomas have signal characteristics similar to those of subcutaneous fat, with high signal intensity on T1-weighted images and moderate signal intensity on T2-weighted images.²⁶ A central signal void corresponding to calcification and ossification noted on radiographs may be seen.

Although the previously described signal characteristics are useful in evaluating tumors, traditional criteria such as cortical breakthrough, soft tissue mass, and periosteal reaction remain optimal for determining the degree of a tumor's aggressiveness. Marrow-infiltrative tumors, such as lymphomas, leukemia, metastatic disease, and multiple myeloma, show a decrease in the normal high-signal-intensity marrow on T1-weighted sequences. On T2-weighted and STIR sequences, signal intensity increases. Adjacent soft

Figure 47–69. Osteoid osteoma in a 19-year-old man with symptoms clinically thought to be due to a tibial stress fracture. **A**, Axial CT image obtained through level of the syndesmosis. The nidus is the small lucent lesion (*black circle*). **B**, Axial T1-weighted image obtained through same level as **A**. The low-signal-intensity nidus (*white circle*) is masked by the surrounding marrow edema. **C**, Axial fat-suppressed T2-weighted image. The low-signal-intensity nidus (*white circle*) is unmasked by the bright signal intensity of the surrounding marrow edema. **D**, Sagittal inversion-recovery image reveals the relatively extensive marrow edema around the small nidus (*white circle*).

Figure 47-70. Chondroblastoma in a 16-year-old boy. *A*, Lateral radiograph demonstrates an expansile mass arising from the back of the tibia. *B*, Sagittal T1-weighted image shows that the mass is purely epiphyseal in this nearly skeletally mature patient. *C*, Sagittal T2-weighted image shows heterogeneous bright and isointense signal intensity within the mass as well as edema of the adjacent musculature (arrows). *D*, Sagittal cartilage-sensitive (fat-suppressed 3D gradient-echo) sequence yields signal intensity within this cartilage tumor that is nearly as bright as in the nearby articular hyaline cartilage.

tissue masses may be seen, most commonly in lymphoma and in aggressive subtypes of multiple myeloma.

The Knee

Steven Shankman, Javier Beltran

Magnetic resonance imaging (MRI) has revolutionized our ability to picture the soft tissue structures of the musculoskeletal system. Increased soft tissue contrast coupled with multiplanar slice capability allows visualization of muscles, tendons, ligaments, cartilage, and bone marrow in a way that is unprecedented. Although the knee is a common site for all disorders occurring in and about the joints, most cases requiring MRI are traumatic in nature. The role of computed tomography (CT) in the evaluation of internal derangement of the knee has always been limited because of its inability to depict normal and abnormal soft tissue anatomy accurately. CT remains the modality of choice, however, in certain situations, such as tibial plateau fracture. This chapter emphasizes standard spin-echo MRI of the traumatized knee. Normal anatomy is discussed, and other disorders affecting the knee joint are included.

Technical Considerations

MRI of the knee is performed using a transmit-receive, general-purpose extremity surface coil, available from most companies that manufacture imaging equipment. Quadrature and phase-array coils are also available. Increased spatial resolution and decreased signal-to-noise (S/N) ratio are important advantages of these coils. The knee is placed in full extension in a neutral position. In general, a small field of view of 14 to 16 cm and a 3-mm slice thickness are recommended.

Different institutions use different pulse sequences for knee imaging. When spin-echo, two-dimensional Fourier transform (2D FT) techniques are used, three planes of section (axial, sagittal, and coronal) are obtained. It is convenient to obtain a proton-density-weighted and a T2-weighted set of images in one plane (e.g., repetition time/echo time [TR/TE], 2000/20–80), frequently the sagittal. Proton-density images are probably the most sensitive for detection of meniscal tears. The axial plane can be imaged using T1-weighted pulse sequences (e.g., TR/TE, 500/20) or, alternatively, T2*-weighted, gradient-echo techniques, which allow good visualization of the articular cartilage (e.g., TR/TE/flip angle, 400/9/75). The same T2* sequence can be used in the coronal plane. Coronal proton-density, fat-suppressed, high-resolution images provide high sensitivity for bone marrow lesions in addition to meniscal tears.

An alternative for articular cartilage imaging is the use of fat-suppressed, spoiled gradient-echo technique; more recently, fast spin-echo T2-weighted images have demonstrated high accuracy for detection of cartilage lesions. Software developments allow fast spin-echo techniques that produce similar contrast in a fraction of the time it takes

to obtain classic spin-echo sequences (e.g., TR/TE, 3600/20–80).

Alternatively, radial imaging can be used, with multiple oblique planes oriented in a radial fashion and centered over each side of the tibial plateau, with extra sections oriented along the axis of the anterior cruciate ligament (ACL). This technique can be used also with 2D FT gradient-echo pulse sequences and provides images similar to those obtained with conventional arthrography.

Three-dimensional Fourier transform (3D FT) volume-acquisition techniques are becoming more popular as a result of software improvements and availability of workstations. These techniques are performed using gradient-echo pulse sequences with short TR/TE (e.g., TR/TE/flip angle, 18/9/30). The advantages of 3D-FT data acquisition include improved S/N ratio and reconstruction of true contiguous slices of about 1 mm in infinite planes of section with minimal distortion.

Finally, for kinematic studies of the femoropatellar joint for patellar tracking abnormalities, multiple images can be obtained with ultrafast gradient-echo techniques in the axial plane during active flexion and extension of the knee within the gantry.

Menisci Anatomy

The menisci of the knee are two semilunar, C-shaped fibrocartilaginous disks that sit on the peripheral margins of the essentially flat tibial plateau. The upper surfaces of both menisci are concave, and they articulate with the convex femoral condyles. Both menisci measure approximately 4 to 7 mm in height at the periphery and 1 mm or less at the free edge. The peripheral one third contains neurovascular structures, whereas the remaining two thirds is strictly fibrocartilaginous.

The lateral meniscus has the same width throughout, approximately 7 to 10 mm. It is shaped like a three-quarter circle, with its anterior and posterior horns attached to the tibia immediately in front of and behind the intercondylar eminence. The central attachment sites are narrower. The peripheral margin of the lateral meniscus is attached to the capsule except posterolaterally, where the popliteal tendon crosses it, and more posteriorly and centrally near the central attachment site, where the capsule does not extend anteriorly into the joint.

The medial meniscus is shaped more like a half-circle. Although its posterior horn is attached to the tibia just posterior to the posterior lateral meniscal attachment, its anterior horn attaches far anteriorly, approximately 10 to

Figure 48-1. Normal anatomy. ACL, anterior cruciate ligament; BF, biceps femoris; Glat, gastrocnemius lateral head; Gmed, gastrocnemius medial head; GT, gracilis tendon; ITB, iliotibial band; LCL, lateral collateral ligament; LH, ligament of Humphrey; LM, lateral meniscus; LW, ligament of Wrisberg; MCL, medial collateral ligament; MM, medial meniscus; PCL, posterior cruciate ligament; PL, patellar ligament; PM, plantaris muscle; PN, peroneal nerve; PT, popliteus tendon; S, sartorius; SM, semimembranosus; ST, semitendinosus; TL, transverse ligament.

Figure 48-2. Normal anatomy. AC, articular cartilage; ACL, anterior cruciate ligament; LCL, lateral collateral ligament; LM, lateral meniscus; LW, ligament of Wrisberg; MCL, medial collateral ligament; MM, medial meniscus; PCL, posterior cruciate ligament; PT, popliteus tendon; TL, transverse ligament.

Figure 48-3. Normal sagittal sequence. The anterior and posterior horns of both menisci are best seen on sagittal views, as are the anterior and posterior cruciate ligaments. Note the "bowtie" configuration of the lateral meniscus owing to its smaller radius of curvature and the far anterior extent of the medial meniscus. A, Long black arrow, lateral meniscus ("bowtie" configuration); small black arrow, transverse ligament; small white arrow, popliteus tendon sheath. B, Curved black arrow, quadriceps tendon; curved white arrow, patellar ligament; medium black arrow, anterior cruciate ligament; small white arrow, ligament of Humphrey; long white arrow, posterior cruciate ligament. C, Small black arrow, Anterior horn of medial meniscus.

14 mm anterior to the anterior horn of the lateral meniscus. The width of the medial meniscus, in contrast to the lateral meniscus, gradually tapers from posterior to anterior. The peripheral margin of the medial meniscus is more firmly attached to the joint capsule and to the tibial plateau itself, the latter via the coronary ligament. As on the lateral side, the capsule does not extend anteriorly into the joint near the posterior central attachment site.

The transverse ligament connects the anterior horns of both menisci. Its thickness varies from 1 to 4 mm. It arises at the most anterior-superior portion of the lateral meniscus and crosses in front of the ACL tibial attachment, merging with the superior portion of the posterior aspect of the anterior horn of the medial meniscus.

The menisiofemoral ligaments are inconstant, 3- to 4-mm fibrous bands arising from the posterior horn of the lateral meniscus and attaching to the lateral aspect of the medial femoral condyle. The ligaments of Humphrey and Wrisberg arise together, the former coursing anterior to the posterior cruciate ligament (PCL) and the latter coursing posterior to the PCL (Figs. 48-1 and 48-2).

MRI Appearance

In general, sagittal images best show the anterior and posterior horns of the medial and lateral menisci. Coronal images best show the meniscal bodies (Figs. 48-3 and 48-4).

Sagittal cross-sections show the posterior horn of the medial meniscus as an isosceles triangle, with the sides nearly twice as long as the base. The neurovascular portion of the posterior horn of the medial meniscus is extensive, sometimes measuring 4 to 6 mm in width (Fig. 48-5).

The anterior horn of the medial meniscus is about one-half the width of the posterior horn, appearing more like

an equilateral triangle. It may vary in its appearance, sometimes seeming almost rounded. It sits on the extreme edge of the anterior tibia, the transverse ligament joining it more superiorly and somewhat posteriorly. This junction may create an arrowhead appearance, pointing posteriorly. The lower portion represents the anterior horn attachment site, and the upper portion represents the transverse ligament junction (Fig. 48-6).

On the lateral side, the transverse ligament attaches to the most anterior-superior aspect of the anterior horn. It may appear as a round dot anterior to the meniscus and should not be confused with a tear (Figs. 48-7 to 48-9).¹⁸ The anterior horn of the lateral meniscus is, in fact, the uncommon site of a meniscal tear. The anterior horn of the lateral meniscus may also demonstrate a striated or speckled, increased-signal-intensity pattern on proton-density images. This normal variation may represent dense collagenous fibers of the anterior cruciate ligament intertwined with the fibrocartilage of the meniscus itself (Fig. 48-10).⁴⁶ The anterior and posterior horns of the lateral meniscus are about equal in size, although the anterior is slightly smaller; both resemble isosceles triangles.

The posterior horn of the lateral meniscus differs from the medial, in that its attachment to the capsule is interrupted by the popliteal tendon, and this should not be mistaken for a tear (Fig. 48-11).¹⁸ The ligament of Wrisberg is usually seen at its origin at the superior margin of the posterior horn. It may appear as a round dot adjacent to the superior aspect of the posterior horn and should not be confused with a tear (Fig. 48-12).⁵⁵

The more peripheral sagittal images show the bodies of the medial and lateral menisci, although not optimally. On both sides, the menisci appear as flat bands. On the lateral side, because of the smaller radius of the curvature, more central slices show a "bowtie" configuration. Volume averaging of the capsule and menisci on slices at the extreme

Figure 48-4. Eight coronal images of the right knee extending from posterior (A) to anterior (B). Normal coronal sequence. The bodies of both menisci are seen best on coronal views, as are the medial and lateral collateral ligaments. Note the decreasing width of the medial meniscus as it courses anteriorly where it attaches at the anterior margin of the tibial plateau. *Smallest arrow*, popliteal artery; *curved arrow*, lateral collateral ligament; *short arrow*, posterior cruciate ligament; *long arrow*, anterior cruciate ligament; *hollow arrow*, iliotibial band; *thick arrow*, medial collateral ligament.

Figure 48-5. Normal peripheral third of the meniscus. Sagittal T1-weighted images reveal normal increased signal intensity at the periphery of the posterior horn of the medial meniscus where neurovascular structures and fatty tissue are present (*arrow*). This may be quite prominent, sometimes measuring 4 to 6 mm in width.

Figure 48-6. Normal anterior horn of the medial meniscus. Sagittal T1-weighted image shows the "arrowhead" configuration of the anterior horn of the medial meniscus. The "arrowhead" points posteriorly, with the lowermost anterior portion representing the anterior horn of the medial meniscus and the higher portion representing the transverse ligament attachment. The cleft in between should not be confused with a tear (*arrow*).

Figure 48-7. Transverse ligament. Sagittal T1-weighted images show the transverse ligament (*arrow*) joining the anterior horn lateral meniscus. The junction (*small arrow*) should not be confused with a tear.

Figure 48-8. Transverse ligament. Axial T1-weighted image shows the transverse ligament extending from the medial joint compartment to the lateral joint compartment (arrow).

Figure 48-9. Transverse ligament. Coronal T1-weighted image, far anteriorly, shows the transverse ligament extending from the medial to the lateral compartments of the knee (arrow).

Figure 48-10. Sagittal proton-density image shows a speckled or striated increased-signal-intensity pattern at the anterior horn of the lateral meniscus near its central attachment site.

Figure 48-11. Popliteus tendon sagittal view. Sagittal T1-weighted image shows the normal high signal intensity of the popliteus tendon sheath at the posterior horn of the lateral meniscus (double arrow). Also, note the transverse ligament attachment to the anterior horn of the lateral meniscus. The plane between them should not be mistaken for a tear (arrow). The normal indentation of the lateral condylar surface representing the junction of its tibial and patellar articular surfaces should not be confused with an osteochondral fracture. The cartilage and subchondral cortex are intact (curved arrow).

Figure 48-12. Pseudotear posterior horn of the lateral meniscus. Sagittal T1-weighted image shows the takeoff of the ligament of Wrisberg at the posterior horn of the lateral meniscus. The signal between the ligament of Wrisberg and the lateral meniscus itself (arrow) should not be confused with a tear.

periphery may be confused with a tear of the meniscal body (Fig. 48-13).¹⁸ This normal increased signal may also represent truncation artifact. Parallel signal lines are produced in the phase-encoding direction at edges where there is a large, abrupt transition in tissue signal intensity.

Figure 48-13. Far peripheral sagittal pseudotear. Far sagittal T1-weighted image of the medial joint compartment shows normal linear high signal intensity representing volume averaging of the joint capsule, concave surface of the meniscus periphery, and normal fat in between (arrows). This may represent truncation artifact as well.

Figure 48-14. Posterior coronal view. Coronal T1-weighted image shows the posterior horns of both menisci as rather large flat bands that should not be confused with discoid menisci (large black arrows). Of note are the posterior cruciate ligament (small curved arrow), ligament of Wrisberg (small black arrow), fibular collateral ligament (large curved arrow), and popliteus muscle belly (white arrow).

Coronal cross-sections at the midportion of the knee best show the bodies of both menisci. They appear triangular in shape, the lateral slightly larger than the medial. The capsular attachment on the medial side is incorporated into the tibial or medial collateral ligament. A small amount of fat may be interposed between the body of the medial meniscus and the capsule.

Posteriorly, coronal cross-sections show the posterior horns as flat bands. On the lateral side, the popliteal tendon courses upward and laterally at 45 degrees (Figs. 48-14 and 48-15). Synovium extends superiorly and inferiorly

Figure 48-15. Popliteus tendon, coronal view. Coronal T1-weighted image, far posteriorly, shows the popliteus muscle belly extending laterally (*curved arrow*) and the popliteus tendon itself (*straight arrow*) crossing through the posterior horn of the lateral meniscus.

about the tendon through the opening in the capsule. It appears as increased signal intensity and is linear in nature. This is seen on both sagittal and coronal images as medium signal intensity on T1-weighted and spin-density images and as high signal intensity on T2-weighted images.

More anteriorly, coronal images show the anterior horn of the lateral meniscus as bandlike. The anterior horn of the medial meniscus is quite small and extends more anteriorly than the lateral.

The avascular portions of the normal menisci and the transverse and meniscofemoral ligaments appear dark, without signal on all pulse sequences. The peripheral vascular zones are of low to medium signal intensity on T1-weighted and spin-density images and are of medium to high signal intensity on T2-weighted images. This is most prominent at the posterior horn of the medial meniscus and is seen best on sagittal images. With increasing age, degeneration leads to indistinct focal areas of medium to high signal intensity in the avascular portion of the menisci.¹⁹

Meniscal Trauma

Traumatic meniscal tears are usually longitudinal, produced when the femoral condyle compresses the meniscus, usually superiorly to inferiorly, posteriorly to anteriorly, and from outside inward. These tears may extend along the radius of the meniscus or may be localized to one segment, usually the posterior horn, and are often referred to as radial or "parrot beak" tears. An extensive tear with central displacement of the free edge is referred to as a "bucket-handle" tear, the handle representing the displaced free margin. Tears with displacement of a portion of meniscal tissue are referred to as *flap tears*. Incomplete partial-thickness tears are usually seen at the posterior horn and extend to an articular surface, usually the inferior one.

Meniscal tears may result in abnormal signal within the meniscus, abnormal size and shape of the meniscus, and abnormal position of meniscal fragments.

Increased signal intensity representing a torn meniscus is best seen on T1-weighted and proton-density images and

may not be seen on T2-weighted images. These T2-weighted images are more helpful when synovial fluid insinuates itself within the tear. Such signal changes represent a torn meniscus only when the signal extends to the superior or inferior articular surface (Figs. 48-16 and 48-17). The periphery of the meniscus does not represent such a surface. Such findings may be seen on only one image or in only one plane. Altering the gray scale of an image should be done cautiously, because false-positive images result from exaggeration of intrameniscal signal. When it is not clear whether signal extends to the articular surface, a true tear is probably not present. Controversy exists about whether intrameniscal signal, globular or linear, represents degeneration, since many such cases are seen to have resolved at follow-up examination. Of note, however, is the "meniscus-within-a-meniscus" appearance, in which increased signal is seen throughout the meniscus cross-section. This represents a meniscal tear approximately 50% of the time (Fig. 48-18).

Figure 48-16. Nondisplaced meniscal tears. Sagittal T1-weighted image shows high signal intensity at the posterior horn of the medial meniscus extending to the inferior articular surface (*arrow*).

Figure 48-17. A and B, Sagittal proton-density images show curvilinear increased signal at the posterior horn of the medial meniscus extending to the articular surfaces, indicative of a tear.

Nondisplaced peripheral separations may be difficult to detect. The most specific finding is irregular, jagged, increased signal intensity at the periphery that brightens on T2-weighted images (Fig. 48-19).

More extensive tears may alter the size, shape, and position of the meniscus. When a portion of the free margin of the meniscus is detached (a bucket-handle tear), the remaining peripheral portion appears small and often truncated. The displaced portion usually lies in the intercondylar notch beneath the ACL or the PCL (Figs. 48-20 and 48-21). Occasionally, it may flip anteriorly above the ante-

rior horn (Fig. 48-22). Coronal views are helpful in further identifying such displaced fragments, which should not be confused with the central attachment sites of posterior meniscal horns.

Small radial tears of the free edge, almost always seen laterally (as parrot beak tears), are best seen on coronal images. On sagittal views, the “bowtie” configuration of the lateral meniscus may be disrupted centrally (Fig. 48-23).^{4, 13, 35, 36, 53}

Thin-section CT of the menisci after air-contrast arthrography has been used for evaluation of tears. This technique has had limited acceptance, with conventional arthrography favored until the advent of MRI.

Postoperative Appearance

The MRI appearance of the postsurgical meniscus depends on the nature of the surgical intervention. After partial meniscectomy, it can be quite difficult to evaluate tearing of the meniscal remnant or incomplete meniscal resection. The MRI appearance of the arthroscopically nor-

Figure 48-18. Meniscus-within-a-meniscus appearance. Sagittal T1-weighted image shows increased signal intensity throughout the confines of the posterior horn of the medial meniscus. Although signal does not extend to the articular surface, a true tear is seen at arthroscopy 50% of the time.

Figure 48-19. Peripheral tear. Sagittal T2-weighted images show high signal intensity at the periphery of the posterior horn of the medial meniscus (arrow). A joint effusion is present.

Figure 48-20. Bucket-handle tear. A, Sagittal T1-weighted images show a bucket-handle tear of the medial meniscus. The central portion is displaced into the intercondylar notch (*large arrow*). Note the distorted size and shape of the peripheral portion (*small arrows*). B, Coronal T1-weighted images show the irregular periphery (*small arrows*) and the displaced central portion (*curved arrows*).

mal meniscal stump varies. The contour may be smooth with homogeneous signal intensity. Standard MRI criteria for meniscal tears are useful only in this situation. Other such “normal” stumps may demonstrate an irregular surface contour with inhomogeneous signal intensity; in fact, such a postoperative appearance represents a normal meniscal remnant most of the time. In such a setting, however, it is nearly impossible to delineate true pathology (Fig. 48-24).⁴⁹

Peripheral meniscal tears are often treated conservatively or with arthroscopic repair. In either situation, in patients who have become asymptomatic and presumably

healed, persistently increased signal intensity at the periphery of the meniscus remains unchanged from that seen on preoperative studies. The presence of such signal, therefore, should not be misinterpreted as a meniscal re-tear. In this regard, some cases of false-positive MRI findings may actually represent older injuries that have healed by the time arthroscopic examination is performed.¹¹

MR arthrography of the knee is recommended when there has been prior meniscectomy or arthroscopic repair of a peripheral tear. Diluted gadolinium can be injected into the knee joint directly or intravenously, with imaging performed after 10 to 15 minutes of moderate exercise.

Figure 48-21. A and B, Sagittal proton-density images show displaced meniscal tissue at the intercondylar notch indicative of the bucket-handle tear. Meniscal tissue beneath the posterior cruciate ligament is known as the PCL sign.

Figure 48-22. Displaced meniscal tear. Sagittal T1-weighted image shows virtual absence of the posterior horn of the lateral meniscus (straight arrow). The displaced fragment (curved arrow) has flipped anterior to the anterior horn of the lateral meniscus.

Figure 48-23. Parrot beak tear. Sagittal T1-weighted image shows increased signal intensity interrupting the "bowtie" configuration of the lateral meniscus (arrow) indicative of a parrot beak tear.

Figure 48-24. Partial resection of the meniscus. Sagittal proton-density image shows partial resection of the posterior horn of the medial meniscus. Note the marked increase in signal within a clinically "normal" stump (arrow).

Contrast insinuates itself into true tears and does not extend into areas of healing (Fig. 48-25). T1-weighted imaging with fat suppression is recommended following the intra-articular injection of a gadolinium saline solution. If a joint effusion is present, a routine MR image of the knee may be diagnostic. Fluid, like contrast, may insinuate itself into a true tear.^{2, 28}

Discoid Meniscus

A *discoid* meniscus refers to a meniscus, almost always the lateral one, that is not C-shaped but disklike; it covers most of the tibial plateau to varying degrees rather than just its periphery. It is prone to tearing and is usually seen in children and adolescents, in whom it may be asymptomatic and noted incidentally. Although the discoid meniscus is seen in youngsters, it is believed to be more developmental than congenital, because the fetal meniscus never assumes such a shape. MRI shows the signal void of the meniscus extending toward the intercondylar notch. Although much has been said about the increased number of routine sagittal images on which the discoid meniscal body is seen (Fig. 48-26), it is simpler to judge such an enlarged meniscus on the coronal view (Fig. 48-27).⁴⁸

Anterior Cruciate Ligament

Anatomy

The ACL extends from its semicircular attachment at the posterior aspect of the medial surface of the lateral femoral condyle to the anterior intercondylar region of the tibia, just medial to the midline, just lateral and anterior to the anterior tibial spine. This attachment is therefore several millimeters posterior to the anterior tibial margin. It is just posterior to the transverse ligament and just anterior

Figure 48–25. Sagittal (*A*) and coronal (*B*) T1-weighted images of the knee following the intra-articular injection of a gadolinium saline solution show contrast material within the posterior horn of the medial meniscus, after partial meniscectomy, indicative of a recurrent tear.

Figure 48–26. Discoid meniscus, sagittal views. Sagittal T2-weighted images show the lateral meniscus extending too far centrally, consistent with a discoid meniscus.

Figure 48–27. Discoid meniscus. *A*, Coronal T1-weighted image shows a large, discoid lateral meniscus extending to the intercondylar notch with internal high signal areas (*arrow*). *B*, Sagittal proton density-weighted image better shows the tear present (*arrow*).

Figure 48-28. Normal anatomy. ACL, anterior cruciate ligament; LCL, lateral collateral ligament; LM, lateral meniscus; MCL, medial collateral ligament; MM, medial meniscus; PCL, posterior cruciate ligament; Prox TFJ, proximal tibial-fibular joint; PT, popliteus tendon.

to the central attachment of the anterior horn of the lateral meniscus where some fibers mix. The tibial attachment is larger than the femoral and fanlike in shape.

The ligament measures approximately 4×1 cm (Figs. 48-28 and 48-29; see Figs. 48-1 and 48-2). It may consist of two or more distinct bundles separated by loose connective tissue and fat, more prominent at the mid- and distal portions. Two distinct bands, the smaller anteromedial and the larger posterolateral, have been identified. The former

Figure 48-29. Normal anatomy. ACL, anterior cruciate ligament; deep PB, deep patellar bursa; LH, ligament of Humphrey; LW, ligament of Wrisberg; PCL, posterior cruciate ligament; PL, patellar ligament; Pre PB, prepatellar bursa; QT, quadriceps tendon; SPB, suprapatellar bursa; Sup PB, superficial patellar bursa.

Figure 48-30. Normal anterior cruciate ligament (ACL). Sagittal T1-weighted image shows a normal low-signal-intensity ACL (arrow). Slight increased signal intensity at the tibial attachment site is normal.

is taut in flexion, and the latter is taut in extension. Synovium covers the entire anterior surface of the ACL.

MRI Appearance

The ACL is best seen on sagittal oblique images with slices parallel to the cortex of the lateral femoral condyle. The knee is usually extended during the examination, and the ligament therefore should appear taut, angled about 60 degrees to the tibial plateau. If the knee is flexed more than 5 degrees, it may appear lax. In general, the ACL may appear as a solid low-signal-intensity band or as three

Figure 48-31. Anterior cruciate ligament (ACL), coronal view. Coronal T1-weighted image shows the fanlike ACL insertion (black arrow). Joint fluid is evident at the suprapatellar gutters (white arrow).

Figure 48-32. Anterior cruciate ligament (ACL)–posterior cruciate ligament (PCL) on the axial view. Axial T1-weighted images show the normal ACL flattened against the lateral femoral condyle (*white arrows*). The PCL is always better seen as a low-signal-intensity structure coursing posteriorly and laterally (*black arrows*).

or four separate low-signal-intensity bundles. The tibial attachment is usually better seen than the femoral attachment because of partial-volume averaging of the proximal ligament with the lateral femoral condyle. Normally, increased signal intensity on T1-weighted and spin-density images at the tibial insertion may be seen, presumably the result of the decreased density of the ligament itself or interposed fat (Fig. 48-30).

Coronal and axial images are also useful in evaluating the ACL. Coronal images show the ACL as a curvilinear

fanlike structure adjacent to the horizontal segment of the PCL, near the medial surface of the lateral femoral condyle (Fig. 48-31). Proximally, the signal intensity is uniformly low, whereas distally it may be slightly increased. Axial images proximally show the ACL as a low-signal-intensity band flattened against the medial surface of the lateral femoral condyle (Fig. 48-32). Distally, the ligament is not as well seen (Figs. 48-32 and 48-33).

All imaging sequences demonstrate fat at the intercondylar notch, adjacent to the ACL origin.

Figure 48-33. Normal axial images. *Horizontal medium black arrow*, biceps femoris muscle and tendon; *horizontal small black arrow*, fibular collateral ligament; *horizontal large black arrow*, conjoined tendon; *vertical long black arrow*, sartorius muscle and tendon; *vertical small black arrow*, gracilis tendon; *vertical medium black arrow*, semimembranosus muscle and tendon; *small curved black arrow*, semitendinosus tendon; *large curved black arrow*, posterior cruciate ligament; *looped black arrow*, patellar ligament; *vertical white arrow*, gastrocnemius muscle, lateral head; *horizontal white arrow*, gastrocnemius muscle, medial head; *horizontal hollow arrow*, lateral patellar retinaculum; *vertical hollow arrow*, popliteal artery and vein; *curved hollow arrow*, medial patellar retinaculum; *oblique black arrow*, anterior cruciate ligament.

Trauma

Tears of the ACL occur more commonly at its proximal portion. Complete or partial avulsions occur more commonly at the femoral origin, whereas avulsion fractures are more common at the tibial insertion (Fig. 48–34).

The MRI appearance of an ACL tear varies according to the extent and chronicity of the injury. The more common acute, complete, interstitial tear appears as a fairly diffuse mass of reactive edema and hemorrhage rather than as a discrete structure with a tear within (Fig. 48–35). With time, usually 6 to 8 weeks, and subsequent resolution, the ligament itself may be seen as bowed (Fig. 48–36) or dropped within the intercondylar notch (Fig. 48–37). At times, such a ligament may scar near its origin and appear virtually normal and yet be insufficient. Smaller tears may cause no contour abnormalities but may lead to obscuration of the fasciculi within the ligament.

Indirect or secondary signs of ACL tear include buckling of the PCL, anterior translation of the tibia relative to the femur (Fig. 48–38), posterior displacement of the lateral meniscus from the tibial plateau, indentation of the anterior margin of the medial femoral condyle, and fairly specific combinations of bone contusions (described later). These, in fact, are manifestations of abnormal bony contact at the time of injury and subsequent instability.^{8, 14, 32, 44, 55}

Chronic incomplete tears of the ACL may cause laxity. Diffuse, nonhomogeneous, moderately increased signal intensity may be present on the T1-weighted and spin-density images. The ligament itself may have an indistinct margin or may not be seen at all. Occasionally, a chronic tear may demonstrate a normal MRI appearance as a result of scar formation.

It should be stressed that the normal ACL may not be seen well on routine sagittal oblique images. The ligament may, at times, be seen best on coronal and axial images.

Figure 48–34. Sagittal T2-weighted image shows avulsion fracture at the anterior cruciate ligament (ACL) tibial insertion. The ACL is retracted, not taut, but intact.

Figure 48–35. Sagittal proton-density image shows a complete interstitial tear of the anterior cruciate ligament manifest as fullness (edema or hemorrhage) at the intercondylar notch.

Correlation of the different imaging planes is always essential (Fig. 48–39).^{20, 31, 43, 56}

Repair

Most ACL repairs are intra-articular and consist of arthroscopic ACL reconstruction with patellar bone central-third patellar tendon tibial bone autografts. MRI demonstrates a well-defined, intact, low-signal-intensity autograft in clinically stable postoperative knees. Revascularization, which takes place 4 to 9 months postoperatively, may increase the signal intensity of the graft, leading to isointensity with the intra-articular space. This may account for apparent discrepancies in graft size. In this regard, focal and diffuse signal changes may be physiologic. Therefore, the object of postoperative evaluation in the first year following surgery is to identify continuity of the graft itself rather than contour deformities or abnormal signal patterns (Fig. 48–40).³⁹ After the first year, graft impingement may appear as increased signal intensity. Impingement precedes graft disruption and is usually secondary to anterior placement of the tibial tunnel.

Localized anterior arthrofibrosis may result from such impingement or from debris raised by drilling the tibial tunnel. Because of its headlike appearance on arthroscopy and its characteristic focal reddish blue discoloration that resembles the eye of Cyclops, it is often referred to as the *Cyclops lesion*. It usually appears as a low-signal-intensity mass surrounded by fluid.⁴¹

Other complications of ACL reconstruction include pa-

Figure 48-36. Anterior cruciate ligament (ACL) tear. Sagittal T1-weighted image shows buckling of the ACL, with increased signal intensity at its proximal portion, consistent with a tear (*arrow*).

Figure 48-38. Buckling of the posterior cruciate ligament (PCL). Sagittal T1-weighted image shows buckling of the PCL (*arrow*). This is an indirect sign of the anterior cruciate ligament tear present in this patient. Also note anterior subluxation of the tibia.

Figure 48-37. Anterior cruciate ligament (ACL) tear. Sagittal T1-weighted image shows a complete tear of the ACL, which is lying nearly horizontal within the intercondylar notch (*arrow*).

Figure 48-39. Anterior cruciate ligament (ACL) tear on the coronal view. Coronal gradient-echo image shows no identifiable ACL at the intercondylar notch (*small arrow*), indicative of a tear.

Figure 48–40. Anterior cruciate ligament (ACL) reconstruction. Sagittal T2-weighted image shows a normal-appearing ACL repair with patella tendon autograft (arrow). (Photograph courtesy of Dr. Padron, Madrid, Spain.)

tellar fracture and dislodged hardware. The patellar ligament itself may remain thickened.^{4, 40}

Posterior Cruciate Ligament

Anatomy

The PCL arises at the lateral surface of the medial femoral condyle and extends to the posterior surface of the intercondylar region, below the level of the articular tibial plateau. It is wider and thicker than the ACL. It is arcuate in shape when the knee is extended or slightly flexed, and it becomes taut with increasing flexion (see Figs. 48–1, 48–2, 48–28, and 48–29).

MRI Appearance

Sagittal images best show the PCL; it appears as a uniformly low-signal-intensity structure with a nearly horizontal takeoff at the femoral origin and then an abrupt descent at about 45 degrees to the tibia. This angled portion of the ligament is normally directed toward the femur; it is not posterior to it unless the knee is hyperextended. In 20% to 25% of cases, the meniscomfemoral ligaments of Humphrey and Wrisberg are seen as low-signal-intensity dots anterior and posterior to the PCL and should not be mistaken for displaced meniscal fragments (Fig. 48–41).

Trauma

Tears of the PCL are uncommon. Perhaps 50 ACL tears are imaged for each PCL tear. Most are incomplete and occur in the midportion of the ligament. Others involve the tibial insertion, where avulsion fracture may be present. In

Figure 48–41. Normal posterior cruciate ligament (PCL) with the ligament of Humphrey. Sagittal T1-weighted image shows the normal course of the PCL. The anterior low-signal-intensity “dot” represents the ligament of Humphrey in cross-section (arrow).

about 30% of patients, the PCL injury is isolated. In the remaining patients, it is associated with other abnormalities.

Tears of the PCL are best seen on sagittal images. Acute intrasubstance tears produce zones of increased signal intensity secondary to edema and hemorrhage (Fig. 48–42). With disruption or detachment of the ligament, similar signal changes are seen and the ligament itself may appear redundant.^{15, 51, 52} Trauma to the PCL can be seen on axial and coronal images as well (Fig. 48–43).

Medial Collateral Ligament

Anatomy

The medial collateral ligament (MCL) consists of three functional units. The superficial or tibial collateral ligament is a broad, flat band, 2 cm in width and 2 to 4 mm in thickness. The superficial fibers extend from the medial epicondyle of the femur to the tibia, attaching about 2 cm below the joint line and then extending 3 to 4 cm more, distally across the medial concavity of the proximal tibia, where fat and blood vessels are normally present.

The deep fibers, which function as the joint capsule, attach loosely to the periphery of the body of the medial meniscus, where a small bursa or a small amount of fat may intervene. The superior portion constitutes the meniscomfemoral ligament. The firmer attachment to the tibia just below the joint line forms the coronary ligament. A small amount of fat may be present between the superficial and deep fibers of the MCL. In addition, numerous bursae may be present between the MCL and bone and between the MCL and the pes anserinus (Figs. 48–44 to 48–46).

The third unit is composed of the posterior oblique fibers, which blend into the posterior capsule of the knee.

Figure 48-42. Posterior cruciate ligament (PCL) tear. Sagittal T1-weighted image shows no identifiable PCL configuration. Hemorrhage and edema replace the region of a complete tear (*arrow*).

MRI Appearance

The tibial collateral ligament is the portion best seen on coronal images, where it appears as a homogeneously low-signal-intensity structure on all pulse sequences. Moderately increased signal intensity may be seen between the superficial and deep fibers and below the superficial fibers at the distal tibial attachment site, where fat is normally interposed (see Fig. 48-4).

Trauma

Traumatic injuries of the MCL are common and range from *intrasubstance* tears (grade 1 sprain) to *incomplete*

tears (grade 2 sprain) to *complete disruption* (grade 3 sprain). These are best seen on coronal images.

A *grade 1* sprain appears as increased signal intensity within the ligament secondary to intrasubstance edema. Fluid may be seen on both sides of the ligament as well. All of these changes are best noted on spin-density and T2-weighted images. When internal signal extends to the superficial or deep surface, a *grade 2* sprain is diagnosed (Fig. 48-47). A *grade 3* sprain is seen as complete disruption of the low-signal-intensity band with redundancy of its proximal and distal portions. The ligament may be stripped from its femoral and tibial attachments, in which case hemorrhage and edema are seen as increased signal

Figure 48-43. Tear of the posterior cruciate ligament (PCL) on axial and coronal views. Axial T1-weighted images show no identifiable PCL at its origin (*curved arrows*). Gradient-echo coronal images show no identifiable PCL at the intercondylar notch (*small arrows*). The normal anterior cruciate ligament is well defined (*large arrow*).

Figure 48-47. Medial collateral ligament tear. Coronal gradient-echo image shows thickening of the medial collateral ligament with increased signal intensity (curved arrow). This represents a grade 2 sprain with signal extending to the superficial and deep surfaces.

intensity medial to the ligament (Figs. 48-48 and 48-49). This should be distinguished from fluid in the gutters of the suprapatellar bursa.

Bone bruise adjacent to the MCL attachments may be another manifestation of MCL injury, representing microavulsions.^{4, 13, 36, 44}

Lateral Collateral Ligament Anatomy

The lateral or fibular collateral ligament is a tubular cord arising at the lateral epicondyle of the femur above the popliteal groove, and extending inferiorly and posteriorly to the fibular head, where it joins with the biceps femoris insertion, the conjoint tendon (Fig. 48-50). In contrast to the MCL, the lateral collateral ligament is separate and apart from the lateral joint capsule, with the lateral geniculate veins and arteries interposed (see Figs. 48-1, 48-2, 48-28, and 48-44 to 48-46).

Numerous other structures at the lateral aspect of the knee contribute to its stability, including the iliotibial band, the biceps femoris tendon, the fabellofibular ligament, the arcuate ligament, and the popliteal muscle and tendon.⁶¹

MRI Appearance

The lateral collateral ligament is best seen on coronal images, where it appears as a uniformly low-signal-intensity cord on all pulse sequences (see Figs. 48-4 and 48-49).

Figure 48-48. Medial collateral ligament tear, grade 3. Coronal gradient-echo image shows complete disruption of the medial collateral ligament (*curved arrow*). In addition, a normal anterior cruciate ligament is not seen at the intercondylar region and is therefore torn (*small arrow*).

Figure 48-49. Medial collateral ligament tear, grade 3. Coronal T1-weighted image shows complete disruption of the medial collateral ligament (*large arrow*). Edema and hemorrhage surround the ligament. Also, note the origins of the anterior cruciate ligament (*small curved arrow*) and posterior cruciate ligament (*large curved arrow*). Portions of the fibular collateral ligament are seen (*small arrow*).

Figure 48-50. Conjoined tendon. Sagittal T1-weighted image, far lateral, shows the tendon of the biceps femoris (*thick arrow*) inserting with the fibular collateral ligament (*thin arrow*) as the conjoined tendon at the fibular head (*curved arrow*).

Trauma

Injuries to the fibular collateral ligament are usually the result of severe trauma involving varus force. Hemorrhage and edema with or without disruption of the ligament may be present. Signal intensity changes, as expected, reflect the edema present (Figs. 48-51 and 48-52).^{4, 13, 36} Avulsion of the lateral capsule at its tibial insertion is often associated and is referred to as a *Second fracture*, the lateral capsular sign.⁵⁸

CT of the cruciate and collateral ligaments is never routinely performed.

Figure 48-51. Tear of the lateral collateral ligament complex. Axial T1-weighted images show no identifiable fibular collateral ligament. The biceps femoris tendon is irregular proximally and completely torn distally (*curved arrows*). In addition, no identifiable anterior cruciate ligament or posterior cruciate ligament is seen at the intercondylar notch.

Figure 48-52. Lateral collateral ligament tear. Coronal T1-weighted image shows intermediate-signal-intensity replacement of the lateral collateral ligament, which is split, redundant, and discontinuous (arrow).

Pitfalls in Diagnosis

Transverse Ligament

The attachment sites of the transverse ligament to the anterior horns of the medial and lateral menisci may mimic a tear on sagittal views (see Figs. 48-3 and 48-7).

Meniscomfemoral Ligaments

The takeoff of the ligament of Wrisberg at the posterior horn of the lateral meniscus may mimic a meniscal tear on sagittal views. When seen on end at its midportion, it may mimic a joint body posterior to the PCL. Similarly, a thick or low-lying ligament of Humphrey may appear as a displaced meniscal fragment (see Fig. 48-12).

Popliteal Tendon

The popliteal tendon and synovium cross the posterolateral aspect of the posterior horn of the lateral meniscus. The oblique region of increased signal intensity that results should not be confused with a meniscal tear (see Figs. 48-3, 48-4, 48-11, and 48-15).

Central Attachment Sites of the Posterior Menisci

The posterior horns of both menisci at the central attachment sites are not attached to the joint capsule and therefore may appear irregular on sagittal views. The posterior horns are seen on coronal views as flat bands that should not be confused with discoid menisci (see Fig. 48-14).

Meniscocapsular Junction

Far peripheral sagittal sections may show increased signal intensity at the bodies of both menisci because of volume averaging of the normal concavity of the meniscal body periphery with the joint capsule. Coronal images are normal (see Fig. 48-13).

Peripheral Meniscus

Increased signal intensity at the periphery of the meniscus represents the normal neurovascular portion, which can be quite prominent, especially at the posterior horn of the medial meniscus (see Fig. 48-5).

Origin of the Anterior Cruciate Ligament

Sagittal images may demonstrate volume averaging of the ACL and its origin at the lateral femoral condyle. This may mimic a proximal tear. Brightening on T2-weighted images, however, is not seen.

Anterior Horn of the Lateral Meniscus

The anterior horn of the lateral meniscus at its central attachment site often shows a speckled or striated, increased-signal-intensity pattern on proton-density images (see Fig. 48-10), which should not be confused with a tear. This pattern may represent dense collagen fibers of the ACL intertwined with the fibrocartilaginous meniscus. Isolated tears of the anterior horn of the lateral meniscus are less common than this normal variation.

Bone and Bone Marrow

The cortical bone of the distal femur, proximal tibia, and patella is of low signal intensity on all pulse sequences.

The signal intensity of the medullary canal reflects the changing amounts of hematopoietic and fatty bone marrow with age; the fatty marrow increases with time. Older patients may have residual islands of hematopoietic marrow, which should not be confused with infiltrative disease. The epiphyseal portions of the distal femur and the proximal tibia, and the epiphyseal patella always contain predominantly fatty marrow. The sensitivity of MRI to bone marrow alterations makes it ideal for detecting traumatic injuries.

Essentially four types of bone injury occur about the knee:

- Bone bruise or contusion
- Osteochondral fracture
- Stress fracture
- Obvious fractures of the femoral shaft, tibial plateau, and patella.

Some of these are occult; others are not (Fig. 48-53).

Figure 48-53. Sagittal proton-density image shows curvilinear low signal intensity at the proximal tibial epiphysis, indicative of nondisplaced fracture.

Bone Bruises

A bone bruise represents an acute, occult microfracture of subchondral trabecular bone with subsequent hemorrhage and edema. The cortex and articular cartilage are intact. They may be secondary to direct trauma or associated with twisting injuries and internal derangement of the knee; they resolve in 6 to 8 weeks. These injuries, which were not apparent before MRI became available, appear as ill-defined, subchondral, reticulated or stellate regions of

low signal intensity on T1-weighted images and high signal intensity on T2-weighted images (Fig. 48-54).^{29, 34, 60}

Osteochondral Fractures

An *acute* osteochondral fracture may be displaced or impacted:

1. *Displaced* osteochondral fragments are best seen on T2-weighted images, especially if a joint effusion is present. These are often seen at the medial patellar facet and the anterolateral femoral condyle secondary to patellar femoral dislocation (Fig. 48-55).
2. *Impacted* osteochondral lesions are commonly seen at the anterolateral femoral condyle. Decreased signal intensity is seen on T1-weighted images at the impaction site; increased signal intensity is seen about the impaction site on T2-weighted images as a result of edema. The overlying cartilage may be intact (Fig. 48-56).^{29, 34, 57}

Chronic osteochondral fractures (osteochondritis dissecans) are well visualized with MRI. Some believe that increased signal intensity at the base of the osteochondral fracture on T2-weighted images represents a loose or unstable fragment.¹⁰ Evaluation by MRI of the overlying cartilage, however, remains less reliable (Figs. 48-57 and 48-58).^{29, 57}

CT arthrography may delineate acute and chronic osteochondral defects, but it is also unreliable.

Stress Fracture

Stress fractures may be occult. They appear as linear, low-signal-intensity bands, away from the joint on T1-weighted and T2-weighted images. Increased signal intensity may be seen about the impacted fracture site on T2-

Figure 48-54. Bone bruise. **A**, Coronal T1-weighted image shows an ill-defined, subchondral, reticulated or stellate region of low signal intensity beneath the lateral tibial plateau (black arrow). Fluid is seen at the suprapatellar bursa, at the lateral gutter (white arrow). **B**, Sagittal T2-weighted image shows increased signal intensity indicative of edema or hemorrhage (arrow).

Figure 48-55. Displaced osteochondral fracture. *A*, Sagittal T2-weighted image shows a large osteochondral defect at the posterior aspect of the lateral femoral condyle (*arrow*). A large joint effusion is present. *B*, Sagittal T2-weighted image more centrally shows the detached bony fragment anteriorly (*arrow*). The low signal intensity of the fragment is suggestive of secondary osteonecrosis.

Figure 48-56. Impacted osteochondral fracture. Sagittal proton-density image shows a small, impacted osteochondral fracture at the medial femoral condyle. Edema surrounds the impacted cortex. Of note is the torn posterior horn of the medial meniscus. Joint effusion is present at the suprapatellar bursa.

Figure 48-57. Osteochondritis dissecans. Coronal gradient-echo image shows an osteochondral defect at the notch aspect of the medial femoral condyle (*arrow*). A defect is seen at the adjacent articular cartilage (*curved arrow*). High signal intensity surrounds the osteochondral fragment. There is controversy as to whether this represents a loose fragment or a healing one. Of note is the fanlike insertion of the anterior cruciate ligament. Also, note the medial collateral ligament and iliotibial band.

Figure 48-58. Osteochondritis dissecans. Sagittal proton-density-weighted and T2-weighted images show an osteochondral defect (arrow) at the notch aspect of the medial femoral condyle. The overlying cortex appears intact. High signal intensity at the base of the defect may represent granulation tissue or may suggest loosening.

weighted images, reflecting the associated edema (Fig. 48-59).²⁶

CT may detect stress fractures, especially those that are longitudinal (Fig. 48-60).¹

Tibial Plateau Fractures

Tibial plateau fractures result from extreme valgus force at the knee and represent a common type of knee injury. Both CT and MRI can define the fracture and the degree of depression. Because osseous detail is better seen with CT, tibial plateau fractures are often best studied in this manner, complemented with 2D and 3D reconstructions. Fracture fragmentation, displacement, and depression may be seen more clearly (Fig. 48-61).^{3, 24, 33, 38} MRI, of course, allows visualization of the cruciate and collateral ligaments and menisci.

Patterns of Injury

Although the structures of the knee and their injuries have been discussed separately, most traumatic injuries to the knee result in patterns of injury involving multiple structures.

The ACL principally resists anterior translation of the tibia and secondarily resists internal tibial rotation. This explains why twisting injuries of the ACL occur without direct trauma. Such injuries usually involve valgus stress as well. As a result, tearing of the ACL may be associated with distractive forces at the medial joint compartment and compressive forces at the lateral joint compartment. Distraction may produce injuries to the peripheral medial meniscus and the MCL. Compressive forces may produce

lateral meniscus tears, bone contusion, or osteochondral fracture at the lateral femoral condyle and posterior-lateral tibia. These two articular surfaces are in contact only after an ACL tear and internal rotation of the tibia. Bony injury at the posterior-lateral tibia always occurs in these situations, whereas the lateral femoral condyle may be spared. Therefore, the pattern of posterior-lateral tibial injury with or without lateral femoral injury suggests an ACL tear (Fig. 48-62).⁵⁴

A less common mechanism of ACL tear involves hyperextension without rotation. This mechanism allows impaction at the anterior femoral condyle and anterior tibia without injury to the menisci or collateral ligaments. Hence, this pattern of “kissing” contusions suggests an isolated ACL tear.

The least common mechanism of ACL injury involves varus stress and external rotation of the tibia. As expected, distractive forces result at the lateral joint compartment, and compressive forces are seen medially. Typically, there is disruption of the lateral collateral ligament complex. Avulsion fracture of the lateral capsule at the tibia (a Second fracture) is associated with an ACL tear more than 90% of the time. MRI may not show the fracture fragment itself, but edematous changes at the lateral tibial rim are always present and suggest the presence of an ACL tear.^{22, 37, 42}

The PCL resists posterior translation of the tibia. Car accidents and sports activity are the two most common causes of PCL injury. A direct blow to the anterior tibia when the knee is flexed forcefully displaces the tibia posteriorly, causing a midsubstance tear of the PCL. A fall on the hyperflexed knee may also drive the tibia posteriorly. Bone contusion may result at the anterior tibial plateau and the posterior femoral condyles.^{51, 52}

Figure 48-59. Stress fracture. *A*, Lateral view of the proximal right leg shows faint periosteal reaction at the posterior aspect of the proximal tibia (*arrow*). *B*, A bone scan shows increased uptake at the posterior aspect of the proximal right tibia. *C*, Sagittal T1-weighted image shows linear signal loss at the proximal tibia, indicative of stress fracture (*arrow*).

Muscles and Tendons

Ten muscles and their respective tendons cross the knee joint. The anterior quadriceps represents the rectus femoris, the vastus medialis, the vastus intermedius, and the vastus lateralis, which insert on the proximal pole of the patella. The anterolateral tensor fasciae latae and its iliotibial band insert at Gerdy's tubercle at the anterolateral tibia. The posterior-lateral biceps femoris inserts with the fibular collateral ligament as the conjoined tendon at the fibular head. The posterior-medial sartorius, gracilis, and semitendinosus insert at the posterior-medial tibia, proximally at the pes anserinus. The posterior-medial semimembranosus inserts separately, slightly more posteriorly. The medial and lateral heads of the gastrocnemius arise at the posterior supracon-

dylar region of the femur. The popliteal muscle belly rests at the posterior proximal tibia, its tendon coursing intra-articularly through the posterior horn of the lateral meniscus, toward the popliteal groove of the femur. The plantaris muscle originates at the posterior-lateral supracondylar femur, and its tendon, the longest in the body, courses toward the ankle (Fig. 48-63; see Figs. 48-1, 48-29, 48-44 to 48-46, and 48-62).

Extensor Mechanism

The extensor mechanism of the knee includes the quadriceps muscle and tendon, the patellar ligament, and the components of the patellofemoral joint.

Figure 48–60. CT scan of stress fracture. *A*, An anteroposterior radiograph of the proximal left leg shows faint periosteal reaction at the medial proximal tibia (*arrow*). *B* and *C*, Frontal and lateral bone scan shows uptake at the posteromedial proximal tibia. *D*, CT scan shows a linear cleft at the posteromedial cortex of the left tibia (*arrow*), indicative of a fatigue fracture in this marathon runner.

Figure 48–61. Tibial plateau fracture. Axial CT image with sagittal and coronal reconstructions shows the degree of comminution of the tibial plateau fracture. The central depressed fracture is well visualized and appears rotated.

Figure 48–62. Axial proton-density images with fat suppression show contusion at the posterior lateral aspect of the tibial plateau (A) and at the lateral femoral condyle (B). Sagittal proton-density image (C) shows a straight, fairly intact anterior cruciate ligament. Its proximal portion, however, is inferior to the normal origin, indicative of a tear. This is supported by the associated contusion pattern.

Figure 48–63. Normal anatomy. Ant HLM, anterior horn lateral meniscus; deep PB, deep patellar bursa; G lat B, gastrocnemius lateral head bursa; PL, patellar ligament; post HLM, posterior horn lateral meniscus; pre PB, prepatellar bursa; PT, popliteus tendon; QT, quadriceps tendon; SPB, suprapatellar bursa; sup PB, superficial patellar bursa.

Quadriceps Tendon

The rectus femoris, vastus intermedius, vastus medialis, and vastus lateralis muscles converge to insert as the quadriceps tendon at the superior pole of the patella. The fasciae of these four individual muscles combine to varying degrees to form a multilayered structure. The overall thickness of the quadriceps tendon is 8 ± 2 mm. The transverse width of the tendon averages 35 ± 7 mm. Usually, the vastus medialis and the vastus lateralis merge, producing a three-layered quadriceps tendon, with the fascia from the rectus femoris seen anteriorly and the fascia from the vastus intermedius seen posteriorly. It is also common for the fasciae of the vastus medialis and lateralis muscles to combine with each other and with the fascia of either the rectus femoris or the vastus intermedius muscle, producing a two-layered tendon. This laminar structure can easily be seen on axial and sagittal MRI scans. Attention to these layers is paramount because partial ruptures of the quadriceps tendon tend to involve one of these fascial groups. This may be difficult to detect clinically (Fig. 48–64). Full-thickness tears are more obvious (Fig. 48–65).⁶²

Patellar Ligament

The patellar ligament extends from the distal pole of the patella to the anterior tibial tubercle. Its sagittal dimension is 3.7 ± 1.2 mm proximally, 4.3 ± 1.1 mm at the

Figure 48-64. Partial tear of the quadriceps tendon. Sagittal T1-weighted image shows increased signal intensity at the proximal portion of the quadriceps tendon indicative of partial tearing (arrow). The fasciae from the vastus medialis and vastus lateralis are involved with sparing of the fasciae from the rectus femoris and vastus intermedius muscles.

midportion, and 5.6 ± 1 mm distally. It is a fairly uniformly low-signal-intensity structure seen best on sagittal images. The syndrome of patellar tendinitis represents partial tearing and degeneration, usually of the proximal portion with secondary inflammation. Increased thickness of the proximal part, thicker than 7 mm, is the greatest indication of disease in symptomatic patients (Fig. 48-66). Other findings include an indistinct margin with increased signal changes.¹² It has been shown, however, that these same changes can be seen in asymptomatic individuals.⁴⁵ Complete rupture leads to discontinuity, redundancy, and retraction of the ligament.

Damage to the quadriceps tendon and patellar ligament may be caused by trauma or chronic overuse or may be

Figure 48-66. Patellar tendinitis. Sagittal T1-weighted image shows thickening of the patellar ligament proximally (arrow).

secondary to underlying systemic illness, such as diabetes, hyperparathyroidism, gout, and rheumatic diseases. Damage to the patellofemoral articulation may be secondary to malalignment and tracking problems.

Patellofemoral Joint

Patellar tracking abnormalities can be imaged with axial CT or MRI of the patellofemoral joints performed during incremental knee flexion. Both modalities show the relationship of the patella to the femoral trochlear sulcus during the initial 30 degrees of flexion when most pathology is evident. MRI better defines the medial and lateral retinacula, although CT may image these structures as well. The patellar cartilage itself is better seen with MRI. CT arthrography may be helpful in evaluating gross cartilage defects.

Figure 48-65. Quadriceps tendon rupture. Sagittal proton-density-weighted and T2-weighted images show complete disruption of the quadriceps tendon (black arrow). Incidentally noted is a prepatellar bursitis (white arrow).

Figure 48-67. Patellofemoral instability. Axial CT images of the patellar femoral joints show bilateral patellofemoral subluxation. Note the medial and lateral retinacula, neither of which appears taut.

At 0 degrees of flexion, the patellofemoral joint is not congruent with the patella laterally displaced. With increasing flexion, the medial and lateral retinacula tighten and the patella descends toward the midline. Eventually, congruence of the patella and the trochlea is reached. In a normal knee, this state of patellofemoral congruence is reached with a lesser degree of flexion than in an abnormal knee. There remains then a wide range of what is considered normal. Additional factors contributing to patellofemoral malalignment include structural abnormalities, such as misshapen patella, hypoplastic femoral trochlear sulcus, and abnormally high position of the patella itself (Figs. 48-67 to 48-69).^{47, 50}

Transient lateral patellofemoral dislocation may often be diagnosed from a constellation of findings associated with the injury. These include disruption of the medial patellar retinaculum and the capsule as the capsule is drawn laterally, and contusion at the medial patella and lateral femoral condyle as the patella reduces. Osteochondral lesions and loose joint bodies may result. These most frequently arise at the medial patellar facet (Fig. 48-70).⁵⁰

Articular Cartilage

Because degeneration of the patellar cartilage is such a common problem in young and older individuals, it has

Figure 48-68. Patellofemoral instability. Axial CT scan shows bilateral patellar femoral subluxation. The femoral trochlea grooves are shallow. A joint effusion is noted on the left.

Figure 48-69. Patellofemoral dislocation. Axial CT scan of the right knee in this patient with cerebral palsy shows chronic patellofemoral dislocation. The femoral trochlear sulcus is hypoplastic.

been extensively studied. The term *chondromalacia patella* has been used for both actual cartilage softening and the clinical syndrome of patellofemoral pain in adolescents and young adults.

The degree to which standard spin-echo sequences predict the stages of patellar cartilage degeneration, however, remains controversial. On the basis of these routine protocols for evaluating internal derangement of the knee, certain conclusions can be drawn:

1. The articular cartilage is of uniformly low-to-intermediate signal intensity on T1-weighted, spin-density, and T2-weighted images.
2. Focal signal intensity changes appear to represent localized cartilaginous defects, especially when multiple pulse sequences are used.
3. Spin-density images alone are relatively insensitive to cartilage abnormalities. Normal-appearing cartilage may underestimate the degree of disease present.

These conclusions can apparently be applied to evaluation of the femoral and tibial cartilage as well. Although the consensus is that MRI is best suited for the evaluation of articular cartilage, different pulse sequences may be required.^{9, 16, 17, 21, 31}

Fat-suppressed 3D spoiled gradient-echo MRI is currently in favor. Even here, however, early morphologic defects and cartilage softening are not seen with high sensitivity.³⁰

Inversion recovery sequences, chemical shift selective techniques, and numerous gradient-echo sequences have been proposed. MR arthrography using a dilute gadolinium solution has been investigated. A less invasive technique involving intravenous gadolinium injection followed by diffusion of the agent across the synovium into preexisting joint effusion appears to produce an arthrographic effect within 15 minutes.

Known pitfalls in the evaluation of articular cartilage include the chemical shift and volume-averaging artifacts. The spatial misrepresentation of the interface of predomi-

Figure 48-70. A and B, Axial proton-density images with fat suppression show contusion at the lateral femoral condyle and a chondral fracture at patella apex, after patellofemoral dislocation.

nantly water-containing and fat-containing tissues occurs in the frequency-encoding direction. Therefore, cartilage whose surface is perpendicular to the frequency-encoding axis appears thicker or thinner than it actually is. This artifact may be reduced by decreasing the field of view or by repeating the imaging sequence after rotating the frequency and phase-encoding gradients.

Volume averaging occurs whenever the imaged interface is not perpendicular to the imaging plane. The curved surfaces of the patella and femoral condylar cartilage are thus prone to such artifacts. Imaging in at least two planes may be necessary. Also, the femoral and tibial cartilage is thinner than the patellar cartilage and hence more susceptible to volume averaging.

Bursae

Numerous bursae are present about the knee joint. Anteriorly, two superficial bursae sit anterior to the extensor mechanism, and the prepatellar bursa is anterior to the patellar ligament. One or two deep patellar bursae sit posterior to the patellar ligament (see Figs. 48-29 and 48-63).

Posteriorly, a bursa resides beneath both the medial and lateral heads of the gastrocnemius. The bursa beneath the medial head is adjacent to and usually connected with the semimembranosus bursa. This gastrocnemius-semimembranosus bursa commonly communicates with the joint itself and represents the so-called popliteal cyst (Fig. 48-71; see Fig. 48-44).

Figure 48-71. Popliteal cyst. Sagittal and coronal T1-weighted images show fluid in the knee joint and popliteal cyst, the latter representing a distended, communicating semimembranosus-medial gastrocnemius bursa. A, The sagittal image shows low-signal-intensity fluid at the "cyst" and suprapatellar bursa (*small arrow*). Normal high-signal-intensity fatty marrow is seen at the epiphyses. B, The axial images show the fluid-filled bursa and its relationship to the semimembranosus tendon (*curved black arrow*) and the medial gastrocnemius tendon (*curved white arrow*).

Figure 48-72. Meniscal cyst. *A* and *B*, Anteroposterior radiographs of the right knee show osteoarthritis with a soft tissue mass medially causing pressure erosion of the proximal medial tibia (*arrow*). *C* and *D*, CT scan shows a fluid-filled mass eroding the adjacent tibia (*arrow*).

Illustration continued on following page

Figure 48-72. *Continued.* E and F, Coronal proton-density-weighted and T2-weighted images show the cystic structure communicating with the osteoarthritic joint. The lateral meniscus is degenerated, and what remains of the medial meniscus has been displaced beyond the joint margins (arrow). A meniscal cyst was found at surgery.

Numerous bursae are present at the lateral and medial aspects of the knee joint. Laterally, one bursa resides between the fibular collateral ligament and the joint capsule, a second between the biceps femoris and the fibular collateral ligament, and a third beneath the iliotibial tract. Medially, bursae reside beneath the tibial collateral ligament and the pes anserinus. A bursa may be present between the superficial and deep fibers of the tibial collateral ligament as well (see Figs. 48-45 and 48-46).

Joint Capsule

The knee is the largest, most complex joint in the body. Its fibrous capsule is just as complex. Anteriorly, the aponeurosis of the vastus medialis and lateralis extends from the medial and lateral margins of the quadriceps tendon, patella, and patellar ligament, posteriorly to the respective tibial and fibular collateral ligaments and the tibial plateau. This anterior portion of the capsule is referred to as the medial and lateral patellar retinacula.

Medially, the fibrous capsule attaches at the femoral condyle just above the articular cartilage and at the tibia just below the plateau. The medial meniscus attaches to the capsule and the tibial collateral ligament complex. The coronary ligament refers to that portion of the capsule that attaches the inferior margin of the peripheral medial meniscus to the tibia.

Laterally, the fibrous capsule attaches at the femoral condyle just above the popliteus tendon groove and at the tibia just below the plateau. The lateral meniscus attaches to the lateral capsule, more loosely than the medial, along its periphery except posteriorly, where the popliteus muscle and tendon interpose. The synovial membrane extends through an opening in the capsule posterolaterally between the popliteal tendon and the meniscus and more inferiorly between the tendon and the tibial cortex, often referred to as the subpopliteal recess.

Nontraumatic Disorders

Nontraumatic conditions affecting the knee joint include (1) the development of cystic masses, (2) proliferative disorders of the synovium, (3) osteonecrosis, (4) inflammatory arthritis, (5) osteoarthritis, and (6) hematopoietic and neoplastic diseases.

Cystic Masses and the Knee

Synovial cysts about the knee represent distended bursae, which may or may not be inflamed. The most commonly encountered is the popliteal cyst, which usually communicates with the joint (see Fig. 48-71). Isolated bursitis is also seen, pes anserinus bursitis representing such an entity. Other cystic masses about the knee include ganglion cysts and meniscal cysts.

Meniscal cysts occur at the joint line and are invariably associated with a degenerative horizontal cleavage tear of the meniscus. Ganglion cysts may or may not have a definable communication with the joint and may occur in atypical locations, attached to tendon sheaths, within muscles, or near the proximal tibiofibular joint.

Before any resection, the cystic nature of such a knee mass must be ascertained. The relationship to the joint must be evaluated, and associated intra-articular disease must be sought. MRI is most suited to study these issues. Generally, cystic lesions on MRI are well circumscribed with smooth walls. Because ganglion and meniscal cysts may contain a gelatinous substance high in protein content, short TR/TE images may not show lower signal intensity.

Meniscal cysts are probably secondary to degenerative tears of the menisci. Synovial fluid is forced through the tear and accumulates at the meniscal capsular junction. The large cysts are seen posteromedially, where they may enlarge without restraint if they are posterior to the tibial collateral ligament (Fig. 48-72). They may be mistaken for popliteal cysts. Laterally, cysts appear to be more contained by the fibular collateral ligament and the iliotibial band and

Figure 48-73. Lateral meniscal cyst. Coronal T1-weighted images show a small lateral meniscal cyst (*large black arrow*) and an associated meniscal tear (*large white arrow*). Note the relative containment by the fibular collateral ligament (*small white arrow*) and the iliotibial band (*small black arrow*).

therefore are usually smaller (Fig. 48-73). The detection of the meniscal tear is essential in that treatment of only the cyst itself results in recurrence.

Ganglion cysts are not associated with meniscal tears but may or may not show communication with the joint capsule. Multiple components may be present. More common locations include the proximal tibiofibular joint and adjacent to the suprapatellar pouch (Fig. 48-74).⁷ Ganglion cysts also occur about the cruciate ligaments and may be related to prior ligament sprain (Fig. 48-75).

Although CT may show fluid-containing structures about the knee, communication with the joint and meniscal tears is not demonstrated.²⁷

Pigmented Villonodular Synovitis

Pigmented villonodular synovitis (PVNS) is a rare mono-articular proliferative disorder of the synovium that occurs in adults. The most common site of involvement is the knee. Although conventional radiographs may show associated pressure erosions of the underlying bone, most cases involving the knee demonstrate normal osseous structures at the time of clinical presentation. Soft tissue masses within the knee joint may be appreciated on plain films.

Figure 48-74. Ganglion cyst. *A*, Anteroposterior and lateral radiographs of the left knee reveal osseous erosion at the lateral aspect of the proximal left tibia. *B*, Sagittal T2-weighted image shows a high-signal-intensity mass at the lateral aspect of the proximal left tibia near the proximal tibial-fibular joint. A ganglion cyst was removed surgically.

Figure 48-75. Sagittal T2-weighted images (A), (fast low-angle shot) coronal 2D FLASH (B), and axial proton-density image with fat suppression (C) show a cruciate ganglion cyst adjacent to the cruciate ligaments.

MRI reveals the proliferative synovial mass throughout the confines of the joint capsule. The signal intensity characteristics may vary as a result of the presence of abundant hemosiderin, inflamed synovium, and joint effusion. Certainly, the presence of multiple areas of low signal intensity on all pulse sequences, especially at the periphery, is a clue to the abundant hemorrhage present (Figs. 48-76 and 48-77). The differential diagnosis, however, includes other disorders that may be accompanied by hemarthrosis, such as hemophilia, synovial hemangioma, and inflammatory arthritis.

CT arthrography shows nonspecific nodular proliferation of the synovium. Osseous erosions are demonstrated.

Synovial Chondromatosis

Synovial chondromatosis represents the other major proliferative disorder of the synovium. Like PVNS, it is a rare monoarticular disease that is seen principally in adults.

Cartilaginous metaplasia of the synovium leads to the production of multiple cartilaginous bodies within the confines of the joint. The knee is most commonly involved. As in PVNS, osseous erosions may be present. Although PVNS virtually never calcifies, cartilaginous bodies are prone to such calcification and ossification. The radiographic appearance of multiple calcified and ossified bodies of similar sizes distributed throughout the confines of the joint capsules is diagnostic of the disorder. When these bodies are not calcified, MRI detects them and is often diagnostic.

CT arthrography shows multiple bodies in the joint as well. Plain CT may detect calcification not apparent on radiographs and thus may differentiate synovial chondromatosis from PVNS.

Osteonecrosis

Spontaneous osteonecrosis of the knee is an idiopathic disorder of middle-aged and older adults that usually af-

Figure 48-76. Pigmented villonodular synovitis (PVNS). *A*, Lateral radiograph shows marked soft tissue prominence within the joint capsule associated with osseous erosions. *B*, Axial CT scan shows mixed attenuation fullness at the suprapatellar bursa. *C* and *D*, Sagittal proton-density-weighted images and T2-weighted images show the extent of the mixed-signal mass within the joint. Persistent low signal areas on both sequences, especially those at the capsular margins, indicate extensive hemosiderin deposition and a probable diagnosis of PVNS.

fects the weight-bearing portion of the medial femoral condyle; it less frequently affects the medial tibial plateau, lateral femoral condyle, and lateral tibial plateau. Its onset is heralded by acute pain. X-ray films are normal for approximately 4 to 6 weeks. MRI, however, usually demonstrates a poorly defined zone of decreased signal intensity on T1-weighted images; a poorly defined ring of moderately high signal intensity may be noted about the lesion (Fig. 48-78). Associated osteoarthritis and degenerative tearing of the medial meniscus may be present. Such

meniscal tears precede the necrotic event.⁶ Of course, degenerative cleavage tears are common in the population susceptible to osteonecrosis of the knee.

Eventually, bone necrosis progresses to fracture and collapse of the subchondral bone with fragmentation of the articular cartilage. Osteoarthritis then may be secondary to the necrosis or may exist coincidentally before the necrotic event.⁵ Current studies suggest that spontaneous osteonecrosis of the knee actually represents a subchondral insufficiency fracture.⁵⁹

Figure 48-77. Pigmented villonodular synovitis. Sagittal proton-density (A) and T2-weighted (B) images show a mixed-signal-intensity mass throughout the joint capsule. Low signal intensity is seen at the periphery on both sequences.

Inflammatory Arthritis

The role of MRI in the care of patients with inflammatory arthritis is controversial. Certainly, MRI can show early erosions. With the aid of gadolinium, it can also differentiate among joint effusion, active pannus formation

and chronic pannus, and fibrosis. Both joint fluid and active pannus brighten on T2-weighted images, but only active pannus significantly enhances after gadolinium administration on T1-weighted images. Fibrotic pannus does not enhance with gadolinium on T1-weighted images and does not brighten on T2-weighted images. These distinctions are important to patient management in some, but not all, centers at this time (Fig. 48-79).²⁵

Osteoarthritis

Osteoarthritis may be present coincidentally when other disorders are sought. Osteophyte formation, subchondral

Figure 48-78. Sagittal proton-density image shows a curvilinear margin at the region of osteonecrosis at the medial femoral condyle.

Figure 48-79. Rheumatoid arthritis. Coronal T1-weighted image shows mixed-signal-intensity pannus within the joint capsule leading to osseous erosions.

Figure 48–80. Osteoarthritis. Coronal T1-weighted image shows marked lateral compartment narrowing, osteophyte formation, and lateral subluxation of the tibia. The lateral meniscus is degenerated, and what remains rests beyond the margin of the joint (arrow).

sclerosis, subchondral cyst formation, and cartilage loss can all be appreciated.

Degeneration of the menisci is independent of degeneration of the femorotibial compartments. It usually precedes the development of osteoarthritis, although it may accelerate the process. Therefore, associated degenerative horizontal cleavage tears of the menisci may be seen. These

represent the extension of internal meniscal disruption to the free edge, inferior articular surface, or capsular margin. The development of meniscal cysts has already been discussed.

With advancing osteoarthritis, what remains of the menisci may become adherent to the marginal osteophytes and eventually extruded beyond the margins of the joint. As the femorotibial compartments narrow, the meniscus may be forced between the joint capsule and underlying bone, often to a point above or below the level of the joint itself (Fig. 48–80).

Hematopoietic and Neoplastic Diseases

As mentioned, MRI is exquisitely sensitive to changes in bone marrow, and hence myeloproliferative disorders, neoplasm, marrow reconversion, and marrow failure are all well visualized. Processes affecting the marrow itself can be imaged long before trabecular bony changes are seen (Fig. 48–81). Such changes are necessary before CT can be of value.

It becomes clear that MRI has become the primary imaging modality of the knee. CT, however, remains helpful in evaluating any lesion characterized by calcification or ossification. As discussed earlier, both CT and MRI are also useful in evaluation of patellofemoral instability and tibial plateau fractures.

Osteoid osteoma remains one bone lesion that is best identified with thin-section CT scanning, often after localization with bone scans (Figs. 48–82 and 48–83).²³ It more clearly defines the tiny nidus, whereas MRI may reveal a more vague region of bone marrow edema. Detection of

Figure 48–81. Lymphoma. A and B, Anteroposterior and lateral radiographs of the right knee are normal.

Illustration continued on following page

Figure 48-81. Continued. C, CT scan of the condylar region shows vague rarefaction. D and E, Sagittal T1-weighted and gradient-echo images show a focal abnormality at the condylar region, which represents non-Hodgkin's lymphoma before gross trabecular destruction.

Figure 48-82. Osteoid osteoma. CT scan of the proximal left leg shows the nidus with central mineralization (arrow).

Figure 48-83. Osteoid osteoma. CT scan of the proximal left leg shows a well-defined nidus with central mineralization and associated periosteal reaction at the posterior aspect of the proximal left tibia (arrow).

tumor calcification or ossification is also more clearly seen with CT scanning and may be missed altogether with MRI. This is particularly useful in the evaluation of other bone-forming tumors and cartilage tumors.

The Hip

Mark D. Murphey, Cheryl A. Petersilge

The hip joint is a large and complex articulation that can be involved by numerous pathologic conditions. These include abnormalities resulting from trauma, infection, avascular necrosis, neoplastic involvement, and synovial-based processes. In addition, manifestations of congenital and developmental anomalies are not infrequently recognized in the hip.

Although radiographs remain the initial imaging technique in most instances, computed tomography (CT) and/or magnetic resonance imaging (MRI) is often the next most valuable radiologic method of evaluation. CT and MRI have two advantages: Both eliminate overlying osseous structures that can restrict assessment with radiographs, and both clearly demonstrate the surrounding soft tissue structures as a result of improved contrast resolution. Unfortunately, clinical evaluation of, and distinction between, the various causes of hip pain usually yields nonspecific and, ultimately, unrewarding results. It is therefore important that we, as radiologists, be aware of the disease manifestations that commonly occur about the hip, as seen on CT scans and MR images. In this chapter, we discuss and illustrate the application of CT and MRI to assessment of pathologic conditions involving the hip joint.

Congenital and Developmental Abnormalities

Developmental Hip Dysplasia

Developmental dysplasia of the hip (DDH), previously termed *congenital hip dysplasia* (CHD), is most often evaluated radiologically by ultrasonography and radiographs. MRI, however, can also be used to evaluate DDH; as with ultrasonography, MRI does not expose these patients to radiation. MRI can be particularly helpful in evaluating patients after unsuccessful initial treatment and in evaluating older children after ossification of the capital femoral epiphysis, a situation in which ultrasonography can be difficult to perform.^{87, 96, 112}

Axial and coronal MR images are most useful, and small surface coils with high spatial resolution are necessary to best evaluate the changes of DDH.⁸⁷ Coronal images allow assessment of the shape of the acetabulum and femoral head coverage. MR images also improve evaluation of surrounding soft tissue structures, including the labrum, iliopsoas tendon, capsular tissue, ligamentum teres, transverse acetabular ligament, and associated fibrofatty pulvinar (Fig. 49-1).¹¹²

Ligamentous structures may invaginate into the joint, not allowing reduction of the articulation.^{29, 112, 195} Normally, the acetabular labrum is a triangular area of fibrocartilage superolaterally. It can also insinuate into the joint and make nonoperative reduction impossible.^{29, 87} The ligaments and labrum have low signal intensity on all pulse sequences and are often accentuated by surrounding joint fluid on long repetition time (TR) images. Capsular tissue has intermediate signal intensity on all pulse sequences.

CT is most useful in evaluation of DDH after intraoperative reduction. Injection of contrast medium into the joint is also often performed at intraoperative reduction. The performance of CT as soon as possible after intraoperative arthrography allows contrast material surrounding the non-ossified femoral head to be identified to help assess alignment and its relationship to the acetabulum.^{5, 29, 93, 115, 153, 161, 195} The adequacy of reduction can then be well evaluated by CT.^{87, 112, 119, 120} The overlying cast, typically present, does not create artifact on CT and helps to limit patient motion.

Conversion Defects (Herniation Pits)

Conversion defects (herniation pits) result from an abrasive effect of the anterior hip capsule in an area of the anterosuperior subcapital region of the femoral neck. This phenomenon is common, affecting 4% to 5% of adults, and occurs in an area where there are often normal cortical defects.^{7, 156, 162} The medullary canal is exposed to erosion from the overlying soft tissue and synovium, which creates a subcortical pit.⁷ This developmental alteration, increasingly recognized on CT scans and MR images, is important to recognize as an incidental finding and typically is not a cause of hip pain. In addition, conversion defects must be distinguished from other pathologic conditions (including osteoid osteoma, avascular necrosis, chronic abscess, and intraosseous ganglion) with which they may be confused.

CT scans and radiographs reveal a subchondral area of soft tissue attenuation replacing the marrow or radiolucency, respectively, with surrounding sclerosis in the anterior subcortical region of the superolateral femoral neck (Fig. 49-2A and B).¹⁶² On MR images, herniation pits show marrow replacement in this subcapital region with a rim of low signal intensity on all pulse sequences corresponding to the area of sclerosis (Fig. 49-2C and D). This appearance is seen best on axial and coronal MR images. Internally, the lesions are composed primarily of fibrocollagenous tissue and cystic components. Lesions show low to intermediate signal intensity on T1-weighted MR images and are of variable appearance on T2-weighted images. (Fig. 49-2D and E).

The opinions and assertions contained herein are the private views of the authors and are not to be construed as official or as reflecting the views of the Departments of the Navy, Army, or Defense.

Figure 49-1. Developmental dysplasia of the right hip in a 12-month-old girl. *A* and *B*, Coronal T1-weighted MR images show delayed ossification of right capital femoral epiphysis (*large arrowheads*) compared with left side (*curved arrow*) and displacement superolaterally. Thickening of the fibrofatty pulvinar (*open arrow*), transverse acetabular ligament (*small arrowheads*), and ligamentum teres (*small arrows*) on the right has limited reduction of the hip; however, the acetabular labrum is not infolded (*large arrow*) to block reduction. (Courtesy of Edgar Colon, M.D.)

Figure 49-2. Conversion defects in asymptomatic patients. *A*, Pelvic radiograph shows large conversion defects bilaterally seen as subcapital lucencies with surrounding sclerosis (*large arrows*). *B*, CT scan shows a small herniation pit in the anterior subchondral region (*small arrows*) with vertical extension toward the cortex. *C* and *D* T1-weighted MR images in the coronal (*C*) and axial (*D*) planes reveal herniation pits as focal areas of marrow replacement (*large arrowheads*). This region reveals a channel-like appearance that extends toward the anterior cortex in the axial plane. *E*, Axial T2-weighted MR image reveals heterogeneous signal intensity in the conversion defect (*small arrowheads*), consistent with both fluid and fibrocollagenous tissue.

Herniation pits, composed predominantly of fibrous tissue, remain low in signal intensity on all MR pulse sequences, whereas those with prominently fluid components show high signal intensity on T2-weighted MR images (see Fig. 49–2E).¹⁵⁶ The connection to the cortex can usually be detected by both CT and MRI (optimally seen in the axial plane) with a linear or channel-like appearance.

Herniation pits range in size from 5 mm to several centimeters and can enlarge over time.¹⁶² The lesion's location and imaging characteristics should allow distinction from other pathologic considerations. Daenen and colleagues studied several patients with symptomatic herniation pits and noted this association with lesions larger than 1 cm in runners.⁴⁸ They postulated that the movement of the iliopsoas muscle may cause progressive invagination of soft tissue and may lead to symptoms in a small percentage of patients.

Proximal Femoral Focal Deficiency

Proximal femoral focal deficiency (PFFD) represents a congenital partial absence of the upper femur with resultant

shortening.¹⁷³ The degree of deficiency of the proximal femur is extremely variable and can be difficult to assess adequately on radiographs.

Only limited use of CT and MRI in evaluating PFFD has been reported in the literature.²⁰⁵ However, assessment is important in presurgical planning to guide orthopedic reconstruction because of the wide variation in the degree of the gap between the femoral head and subtrochanteric femur. This gap may be small with pseudarthrosis, or it may be filled with fibro-osseous tissue or devoid of connecting tissue.¹⁷³ MRI or CT can be used to assess this osseous gap and the femoral head, which is delayed in ossification (Fig. 49–3). These structures and the resultant coxa varus deformity cannot be adequately evaluated with radiographs because the gap is radiolucent, whether it is filled with fibro-osseous tissue or a tissue void.

CT shows the nonossified areas as soft tissue attenuation, although these areas can be difficult to distinguish from surrounding muscle. MRI is more valuable because of improved contrast resolution and multiplanar imaging capability. On MR images, the femoral head, if present, shows intensity of yellow marrow, whereas fibrous tissue is low in signal intensity on all pulse sequences (Fig.

Figure 49–3. Proximal femoral focal deficiency in a 6-year-old child. A, Pelvic radiograph shows deficiency of the proximal femur with lucent cleft in upper portion of remaining femur (*large arrow*). B, Coronal T1-weighted MRI was performed to evaluate for possible surgical reconstruction. The image shows a capital femoral epiphysis, seen as high signal intensity (fatty marrow) not well visualized on the radiograph (*large arrowheads*). The femoral head, however, is not connected to the remainder of the femur, where there is intervening tissue (*open arrow*), and thus cannot be used for reconstruction. C, More posteriorly, a coronal T1-weighted MR image shows the upper femur with a low-signal-intensity gap at its upper extent (*small arrowheads*). D, T2-weighted coronal MR image shows that this area maintains low signal intensity, consistent with fibrous tissue (*small arrows*) rather than pseudoarthrosis, which may show high signal intensity.

49–3B, C, and D). Pseudarthrosis may show linear or bandlike high-intensity fluid on long TR images.¹⁷³ Evaluation of PFFD is often best accomplished with coronal images.

Rotation and Version Deformities

Abnormalities of rotation and version (degree of hip anteversion) may be congenital; more often, however, they are a result of trauma. CT and, more recently, MRI have been used to evaluate both types of abnormalities.^{5, 6, 80, 93, 115, 145, 161, 180} Axial images obtained through the femoral head and neck and additional images of the distal femoral condyles are needed. From these images, measurements are obtained of both femoral eversion and rotational abnormalities. These deformities may require orthopedic correction with the use of osteotomies, and imaging is necessary to direct surgical management.

Labral Abnormalities

Historically, labral abnormalities as a cause of internal hip derangement have been difficult to evaluate both clinically and by imaging. With the advancement of hip arthroscopy, however, labral pathology as a cause of radiographically occult hip pain is not uncommon. In fact, this association was identified in 55% of 94 patients in one study.^{83, 143} Detection of labral tears is important not only to identify the cause of symptoms but also to direct arthroscopic repair to prevent development of secondary osteoarthritis.^{4, 66, 68, 91, 103, 155, 182, 209}

The normal acetabular labrum represents a fibrocartilaginous rim of tissue about the acetabulum. It is triangular in cross-section, arises directly from the acetabulum, is thickest posteriorly, and covers a 5- to 18-degree arc over the superior aspect of the femoral head.^{44, 46, 88, 100, 107}

Two normal focal cartilage defects are seen about the hip: (1) the acetabular notch and (2) the fovea capitis of the femur. The notch is spanned by the transverse ligament, and the labrum blends with this structure. The ligamentum teres lies in the fovea capitis (Fig. 49–4). Several ligaments (i.e., iliofemoral, ischiofemoral, and pubofemoral) reinforce the hip joint capsule. The capsule inserts at the base of the labrum anteriorly and posteriorly, creating small perilabral recesses (see Fig. 49–4). However, the capsule attaches above the labrum superiorly, creating a larger recess in this region.^{59, 101, 160, 224}

The normal labrum is triangular in cross-section and low in signal intensity on all MR pulse sequences. As with the shoulder, however, numerous normal variations in labral appearance may simulate pathology. In two studies, the labra of asymptomatic patients were triangular (in 66% to 80%), rounded (in 11% to 13%), flat (in 9%), or irregular (in 7%).^{1, 121} In addition, both studies showed a reduction in a triangular shaped labrum in older patients, suggesting that this may represent a degenerative phenomenon (from 79%–96% to 41%–62%).^{1, 121}

Absent labra have been described in 1% to 14% of individuals, although the significance of this finding (normal variation versus pathology) is uncertain.^{1, 101, 121} Labra

Figure 49–4. Partial superior labral detachment in a 40-year-old man. Coronal T1-weighted MRI arthrogram shows the superior labrum (arrow) with contrast at the acetabular junction (asterisk) representing partial labral detachment. Small perilabral recess (small arrowheads), ligamentum teres (curved arrow), and transverse ligament (large arrowheads) are also seen.

may have intermediate signal foci on T1-weighted and spin density-weighted MR images in 42% to 58% of patients.^{1, 101, 121} Intermediate and high signal intensity may be seen in 37% and 13% of labra on T2-weighted MR images, respectively.¹⁰¹ These areas may be linear, globular, or curvilinear and may extend to the labral margins.^{101, 121} This increased signal intensity is more common in men, in the superior labrum, and with increasing patient age, suggesting a degenerative process.

Labral pathology is most frequently a tear or detachment, with the latter being the more common (see Fig. 49–4).^{46, 47, 55, 68, 125} The superior and anterior labra are most often affected, while posterior involvement is more common in younger patients.^{46, 47, 68, 144, 160, 182} As with meniscal tears, the defects may be classified as radial in orientation, degenerative, bucket-handle, horizontal cleavage, and peripheral longitudinal.^{125, 158, 160, 169}

Although a description of technique is beyond the scope of this chapter, MR arthrography has increased the sensitivity (90%) and accuracy (91%) in detection of labral pathology versus standard MRI (30% sensitivity, 36% accuracy).^{46, 47} This is primarily a result of the ability to distinguish true pathology from a normal variation. Labral tears are diagnosed by the presence of contrast material in the substance of the labrum. Labral detachment shows contrast material separating a portion of the labrum with or without displacement.

Staging of labral pathology has been described by Czerny and colleagues^{46, 47}:

Stage 0 labra are normal with homogeneous low signal intensity, a triangular shape, and an unremarkable acetabular-labral interface and perilabral sulcus.

Stage 1 labra demonstrate an intralabral signal that does not extend to the labral margin.

Stage 2 labra show contrast material on MR arthrography extending into the labra.

Stage 3 labra reveal detachment.

These stages are further subdivided into A and B, with B showing hypertrophy and obliteration of the perilabral sulcus.

The significance of an abnormal labral shape is more difficult to assess. Absence of the labrum should be considered abnormal except anterosuperiorly. Irregular labral margins may represent degenerative fraying.^{101, 160} Labral hypertrophy is abnormal and may be related to altered mechanics secondary to tear or detachment.

A sulcus between the labrum and underlying acetabulum may be a normal variation and is not uncommon on MR arthrography.^{46, 47, 160, 220} Perilabral cysts are commonly associated with labral pathology, particularly detachments.^{133, 185} These cysts (previously referred to as *ganglia*) may extrinsically erode the adjacent acetabulum, suggesting a more aggressive process on radiographs. There is an increased incidence of perilabral cysts in patients with DDH.^{55, 81, 117, 142} Articular cartilage defects are also commonly associated with labral pathology, although the reliability of MRI in this assessment is uncertain.

Synovial Abnormalities

Abnormalities primarily involving the cartilage and synovium of the hip are common. These include (1) *arthritis*

(osteoarthritis, inflammatory arthropathy) and (2) the more infiltrative disorders, such as *pigmented villonodular synovitis* (PVNS), *synovial chondromatosis*, and *amyloidosis*.

Arthropathy

Radiography remains the primary modality by which arthropathy of the hip is evaluated. However, CT and MRI can provide valuable information about the extent of disease, visualization of the surrounding soft tissue involvement, and a means of identifying other causes of hip pain. Detection of hyaline cartilage thinning and focal defects in osteoarthritis continues to challenge the contrast and spatial resolution capabilities of MRI. The clinical use of the CT and MRI in evaluation of osteoarthritis of the hip continues to be relatively limited.^{28, 127} Rarely, hip osteoarthritis can be rapidly progressive (coxarthrosis), simulating infection or neuropathic disease.¹⁷⁶

Involvement of the hip by inflammatory arthritis, both rheumatoid arthritis and the seronegative spondyloarthropathies, is not infrequent. Because the hip is a relatively noncapacious joint space, radiographs demonstrate erosions relatively early in the disease. MRI and, to a much lesser degree, CT can detect the extent of synovial hypertrophy (*pannus*) that is common to all inflammatory arthritides but not evident on radiographs (Fig. 49–5).^{172, 189, 231}

Pannus generally shows low signal intensity on T1-weighted MR images and high signal intensity on T2-weighted MR images. Pannus can be difficult to differenti-

Figure 49–5. Monoarticular left hip pain of 6 months' duration in a 29-year-old man. A, Radiograph of the pelvis shows mild axial narrowing of the hip without erosions (*large arrow*). B, Coronal T1-weighted MR image shows soft tissue thickening (synovitis) about the hip of intermediate intensity (*small arrowheads*) and acetabular erosion (*large arrowheads*). C, On the T2-weighted coronal MR image, synovitis reveals increased intensity (*small arrowheads*) and heterogeneous signal intensity in the acetabular erosion (*large arrowheads*), suggesting a fibrous component to the tissue. Erosion was not visible by CT (not shown), and low-grade infection could not be excluded. The patient had a history of psoriasis with subsequent development of polyarticular disease, typical of psoriatic arthritis in other joints.

Figure 49-6. CT scan shows an iliopsoas bursal fluid collection (arrowheads) with a higher-attenuation fibrous wall (arrows) resulting from iliopsoas bursitis.

ate from synovial fluid, which is also frequently present with involvement of the hip by inflammatory arthritis. Subtle differences between pannus and synovial fluid may be apparent on both T1-weighted and T2-weighted images. Pannus, compared with synovial fluid, usually shows a slightly higher signal intensity on short TR images and has more heterogeneous and mildly lower signal intensity on long TR images (Fig. 49-5B and C). Intravenous (IV) gadolinium injection can facilitate the distinction.¹⁷² Areas of synovitis and pannus formation enhance dramatically and diffusely after gadolinium injection, whereas synovial fluid shows only peripheral contrast enhancement.^{2, 24, 106} Imaging should be performed early after contrast injection because synovial fluid also shows enhancement by diffusion on delayed images.^{114, 171, 173}

Compared with radiography, both CT and MRI demonstrate osseous erosions more clearly because of improved delineation of exposed cortical surfaces.^{172, 232} In addition, MRI provides multiplanar imaging capabilities. Bursal extensions from the hip joint (Fig. 49-6) can also be detected by CT and MRI and are not infrequently seen in patients with inflammatory arthritis, particularly rheumatoid arthritis.^{131, 132} Pannus may occasionally retain relatively low signal on T2-weighted MR images (Fig. 49-5C). This phenomenon may be the result of hemorrhage and deposition of hemosiderin (paramagnetic effect shortening T2 relaxation time) or fibrosis in more chronic areas of inflammation.^{2, 24} Fibrotic components in pannus are often more prominent in the seronegative spondyloarthropathies and may reflect more inactive disease or therapeutic effect.

Overall, MRI of inflammatory arthritis of the hip can be very useful. It allows determination of the extent of pannus formation as well as the degree of bone erosion and articular cartilage thinning. Knowledge of these factors is important in patient management. MRI can also be used to monitor the effects of therapy by quantitating the volume of pannus.^{171, 173}

Infiltrative Disorders

Pigmented Villonodular Synovitis

PVNS represents benign synovial hypertrophy with a variable degree of histologic components, including villous

or nodular synovial hypertrophy as well as pigment deposition of hemosiderin. PVNS occurs in 2 to 11 individuals per million, with relatively equal incidence in men and women.^{56, 62, 76, 173} It is almost always a monoarticular disease and usually affects individuals in their second to fourth decades of life.

There are two basic forms of PVNS:

1. The *localized* form often involves the fingers and accounts for approximately 75% of cases.^{14, 94, 98} Also referred to as *giant cell tumor of the tendon sheath* (GCTTS), it may involve tenosynovial tissues about the hip.
2. The *diffuse* form frequently affects larger joints.⁵⁶ The knee is most commonly involved, and the hip joint is the second most frequently affected articulation.

The pathogenesis of PVNS is unknown; possible causes include neoplasia, sequelae from a synovial hemangioma, disorders of lipid metabolism, repetitive trauma, and the most commonly supported theory of an inflammatory process. Patients with PVNS often complain of long-standing joint pain and decreased range of motion.

Radiographic changes are more frequently seen with PVNS of the hip than of the knee. This is a result of the relative nondistensibility of the hip joint, with synovial thickening causing early extrinsic pressure erosions in most cases (90% to 95%).⁷⁶ These extrinsic erosions on both sides of the joint are well visualized by both CT and MRI (Fig. 49-7).

Coronal and axial MR images often demonstrate the erosive changes and their relationship to the hip joint to best advantage. CT and MRI reveal nodular synovial masses, and there is associated joint effusion in nearly 80% of cases.¹⁷³ This effusion, when aspirated, is a xanthochromic to brownish-stained bloody fluid. On CT scans, there is soft tissue thickening about the hip, and the synovial-based masses often have higher attenuation than the surrounding muscle because of hemosiderin deposition.^{35, 51} These areas of focal synovial masses are usually associated with localized pockets of joint effusion that may extend into the iliopsoas and obturator bursae. Injection of dilute contrast medium, followed by CT examination, reveals nodular filling defects and synovial thickening identical to the findings at arthrography (Fig. 49-7B).

MRI of the diffuse form of PVNS is usually characteristic.^{21, 95, 108, 132} Synovial thickening with nodular excrescences arising from the joint surface is well delineated on MRI. These areas are of heterogeneous signal intensity on all pulse sequences, with prominent low signal intensity on long TR images (Fig. 49-7C and D). The hypointensity is caused by hemosiderin deposition. Specifically, the unpaired electrons of iron in the ferric state (Fe^{+3}) interact with adjacent water molecules, which results in the shortening of the T2 relaxation time.^{95, 132, 193} These effects are directly related to the square of the magnetic field and are thus accentuated with high-field-strength MR units.^{95, 132, 193} Focal areas of synovial fluid, low intensity on T1-weighted images and high intensity on T2-weighted images, are also usually present within the hip joint involved by PVNS. Typically, these fluid collections in PVNS are surrounded by a peripheral rind of low-intensity hemosiderin-laden tissue on T2-weighted MR images. The areas of synovial

Figure 49-7. The patient is a 27-year-old woman with a 5-year history of left hip pain. *A*, Pelvic radiograph shows extrinsic erosive changes (curved arrows) on both sides of the joint. *B*, CT scans before (*B*, top) and after intra-articular contrast injection (*B*, bottom) also reveal extrinsic erosions of acetabulum and femur (large arrowheads) and soft tissue thickening displacing the contrast (large arrows). *C* and *D*, Axial T1-weighted (*C*) and coronal T2-weighted (*D*) MR images reveal extensive thickening about the hip (small arrowheads), causing extrinsic osseous erosions seen as areas of marrow replacement (small arrows). Most of this material maintains low signal intensity on the long TR/TE image, although pockets of high-signal-intensity fluid are seen on the T2-weighted image. This appearance is due to hemosiderin in this patient with pigmented villonodular synovitis, confirmed at surgical synovectomy.

proliferation are hypervascular and may show significant enhancement after IV contrast injection using either CT or MRI.

The localized form of PVNS infrequently involves the tenosynovial tissues about the hip. GCTTS is more variable in the degree of hemosiderin deposition. CT or MRI may show characteristics similar to those of diffuse PVNS with low signal intensity on T1-weighted and T2-weighted images in cases with extensive hemosiderin.^{14, 94, 98} MRI, however, may be less distinctive in cases of GCTTS by showing significant intermediate to high signal intensity within

a mass adjacent to the hip on long TR images resulting from cases with limited hemosiderin.^{14, 98}

MRI and CT are important in follow-up of patients with PVNS to detect recurrences, which are common. Synovectomy is the usual initial treatment; however, because of the difficulty in removing all synovial tissue, estimates of recurrence are as high as 40% to 50% with the diffuse form.⁶⁹ External radiation therapy and injection of a beta-emitting agent into the joint tagged to radiocolloid, producing a nonsurgical synovectomy, may be used as adjuvant treatment methods.¹⁷³ Recurrent disease is identical in ap-

pearance to the initial characteristics previously described on both CT and MRI.

Synovial Chondromatosis

Synovial chondromatosis is caused by the occurrence of cartilage metaplasia within the synovial membrane.^{146, 219} Although many authors consider this a neoplastic disorder, inflammatory and traumatic etiologies have also been postulated.⁹² The disease is usually seen in those between ages 20 and 50 years and is twice as frequent in men. Typical clinical symptoms include joint pain of long duration and locking with limitation of range of motion.

Cartilage metaplasia within the hyperplastic synovium is seen pathologically in synovial chondromatosis.^{146, 219} These villous nodules often become detached from the synovium and are then free intra-articular bodies. The intra-articular fragments of cartilage may grow, deriving nourishment from synovial fluid, or reattach to the synovial lining, where they may grow or may be reabsorbed. The cartilage fragments may undergo endochondral ossification, at which point the term *synovial osteochondromatosis* is appropriate. The synovial tissue of the tendons or bursa about the hip may also be involved by an identical process termed *tenosynovial* or *bursal chondromatosis*, respectively.⁹⁹

In 70% to 95% of cases of synovial chondromatosis, the cartilage fragments calcify. These areas often have a diagnostic ring-type appearance on radiographs (Fig. 49-8).¹⁷³ CT is often the optimal examination for detecting, characterizing, and localizing these chondroid bodies (Fig. 49-8B).^{25, 30} Smaller chondroid bodies are often solidly calcified on CT scans. CT may reveal ossification of the cartilaginous bodies with a cortical rim and trabecular bone centrally containing yellow marrow. A target appearance may be demonstrated because at times there is a central dot of chondroid tissue with calcification.

The MRI appearance of synovial chondromatosis is variable, depending on the degree of cartilage, calcification, and ossification.^{33, 34, 43} Because hyaline cartilage is composed of 75% to 80% water, noncalcified cartilaginous tissue shows low to intermediate signal intensity on T1-weighted images and very high signal intensity on T2-weighted images.¹¹¹ Calcified intra-articular bodies show low signal intensity on all MR pulse sequences (Fig. 49-8C); however, smaller fragments are better detected by CT or radiographs.^{33, 34, 43} The MRI appearance of ossification is low signal intensity on all pulse sequences if it is composed of cortical bone; if it is composed of trabecular bone, it has the intensity of fat (high signal intensity on T1-weighted images, intermediate signal intensity on T2-weighted images).

A target appearance corresponding to the osteochondral bodies on MRI may also be apparent. MRI and CT may reveal an associated joint effusion. Soft tissue thickening about the hip in the noncalcified areas of cartilage metaplasia reveals attenuation similar to or less than that of muscle on CT scans. On MR images, synovial chondromatosis may show low-signal-intensity areas (corresponding to calcified chondral bodies) on all pulse sequences surrounded by high-signal-intensity fluid or noncalcified cartilage metaplasia on T2-weighted images, an appearance exactly opposite of that of PVNS (see Fig. 49-7 and Fig. 49-8). On

long TR images, low-signal-intensity fibrous septation may be present within the synovial metaplasia. CT and MRI may show extrinsic erosion and secondary osteoarthritis, a finding more common when synovial chondromatosis involves the hip, as opposed to larger joints such as the knee, because of the hip's relative lack of distensibility.^{157, 195, 198}

In rare circumstances, synovial chondromatosis may undergo malignant degeneration to chondrosarcoma.¹⁷³ Identification by CT or MRI of osseous invasion or destruction should suggest this complication.

Multiple intra-articular osteochondral bodies may also be apparent after involvement of the hip joint by infection, trauma, or arthritis. This process, often termed *secondary synovial chondromatosis*, should be distinguished from the primary type by associated changes about the hip joint. In addition, the osteochondral bodies are fewer in number, are more varied in size, and show multiple rings of growth with calcification and ossification, creating an appearance of lamination. This multiple ring appearance is not seen in primary synovial chondromatosis.^{146, 219}

Amyloidosis

Amyloid deposition within the tenosynovial tissue and osseous structures about the hip occurs more commonly with secondary amyloidosis than with primary amyloidosis. Primary amyloidosis is associated with multiple myeloma (5% to 10% of patients) and chronic inflammatory diseases.^{11, 37, 130, 173} Patients with chronic renal failure receiving long-term hemodialysis are being increasingly reported to show a unique form of secondary amyloidosis with deposition of β_2 -microglobulin.^{15, 37, 40, 72}

Camacho and coworkers reported an incidence of amyloidosis of 35% in a group of 88 patients receiving hemodialysis longer than 4 years.³⁶ In the future, however, use of newer membranes in hemodialysis to better filter β_2 -microglobulin may decrease the incidence. All forms of amyloidosis appear to have some proclivity for deposition about the hip, both within bone and within tenosynovial tissue. Osseous lesions usually have a punched-out appearance, are eccentric, or occur from extrinsic erosion, and they reveal a thin sclerotic margin on radiographs and CT scans. MR images show marrow replacement on T1-weighting (Fig. 49-9A).

Femoral lesions often predispose to pathologic fracture. Both CT and MR images reveal diffuse thickening about the joint with intra-articular deposition of amyloid. This thickening has an appearance on CT scans and a signal intensity on T1-weighted MR images similar to those of muscle attenuation. Interestingly, T2-weighted MR images show that the signal intensity within the amyloid deposition remains low to intermediate, although high signal intensity from focal fluid collection is also often present (Fig. 49-9B).^{132, 178} Pathologically, this low signal intensity is probably related to the fibrillar, collagen-like composition of amyloid. Injection of IV contrast material may reveal enhancement of the synovial thickening on CT and MR images (Fig. 49-9C). The MR and CT appearance is similar to that of PVNS; in contrast to monoarticular disease in PVNS, however, amyloidosis is typically polyarticular

Figure 49–8. The patient is a 67-year-old woman with a 2-year history of left hip pain caused by synovial chondromatosis. *A*, Pelvic radiograph shows subtle multifocal areas of calcification about the hip (*large arrowheads*) with extrinsic erosion (*open arrow*). *B*, CT scans, before (*left*) and after (*right*) intra-articular air injection reveal calcifications (*small arrowheads*), some of which have a typical ringlike appearance of cartilage and extrinsic erosion of bone (*open arrow*). After intra-articular injection, nodular soft tissue areas of synovial metaplasia and calcification (*small arrows*) are surrounded by air. *C*, Coronal T1-weighted (*left*) and axial T2-weighted (*right*) MR images show thickening about the hip (*small arrows*) and extrinsic erosion (*open arrow*). High signal intensity on the T2-weighted image represents fluid and synovial metaplasia (*small arrows*), with a filling defect representing a calcified fragment (*curved arrow*).

with bilateral hip involvement reflecting that it is a systemic process.¹⁷³

Hemophilia, an X-linked recessive genetic disorder caused by deficiency of clotting factor, is associated with repetitive, intra-articular, intramuscular, and intraosseous episodes of bleeding.¹⁷³ With each bleeding episode, hemosiderin is progressively deposited within the synovial membrane, ultimately resulting in synovial hypertrophy and

pannus formation. Although hip involvement is not frequent, the hip may show progressive joint destruction and spontaneous dislocation. MRI and CT reveal synovial thickening, and on long TR images the hemosiderin-laden synovial tissue stays low to intermediate in signal intensity, as with PVNS.^{113, 225, 231}

Synovectomy can be helpful in patient treatment; however, it must be performed before cartilage destruction

Figure 49-9. Renal failure in a 43-year-old man undergoing chronic hemodialysis. A and B, Coronal T1-weighted (A) and T2-weighted (B) MR images show thickening of the tissues about both hips (*large arrowheads*) with marrow replacement from acetabular erosions (*small arrow*). The image in B reveals that much of this tissue remains low in signal intensity, although pockets of high intensity fluid (*small arrowheads*) are present. There is a focus of decreased marrow signal from avascular necrosis on the right (*large arrow*). Histologic evaluation of this tissue revealed amyloid deposition. The large mass in the left medial thigh (*asterisk*) in A and B represents a spontaneous hemorrhage resulting from heparin administration during dialysis. The hematoma has areas of high signal intensity on T1-weighted and T2-weighted images with heterogeneity. There is marked associated edema (*open arrows*) on the long TR images owing to hemorrhage dissecting throughout the surrounding tissues. C, Axial T1-weighted preintra- and postintra-venous gadolinium injection also shows extrinsic erosions (*small arrows*) and thickening about the soft tissue of the hip, which enhances with contrast (*large arrowheads*). The changes about the hips are related to amyloid deposition.

occurs. MRI can also be useful in this determination.⁸⁶ In patients with hemophilia, areas of soft tissue or intraosseous hemorrhage also occur about the hips.

Hermann and colleagues described soft tissue hemorrhage on MRI with acute hematoma (1 to 6 days) having an appearance similar to that of muscle on T1-weighted images and having low signal intensity on long TR images.⁸⁶ Beyond 1 week after hemorrhage, signal intensity increases on both T1-weighted and T2-weighted images. These hematomas may subsequently ossify (myositis ossificans or heterotopic bone formation) with cortical bone peripherally and trabecular bone with yellow marrow centrally. This zonal pattern of ossification, beginning peripherally, is distinctive and is best detected in its earliest phases by CT.

Infection

Infection of the bone or soft tissue about the hip or septic arthritis is often very difficult to detect on initial

radiographs. Osseous manifestation of osteomyelitis, such as bone destruction and periosteal reaction, may not be apparent on radiographs for 10 to 14 days after the onset of infection.¹⁷³ The metaphysis of the proximal femur is intra-articular because the hip capsule attaches in the intertrochanteric region. Infection localized to this region, a common pattern in children because of the normal vascular supply, may thus gain rapid access to the joint if the process extends through the osseous cortex.⁷⁴ Bacterial infection of the hip joint can then lead to rapid and irreparable cartilage damage and joint destruction.

Early recognition of osteomyelitis, septic arthritis, and soft tissue abscess about the hip is thus imperative in order to prevent these dire sequelae and to improve clinical outcome. CT and MRI help to distinguish inflammation, such as cellulitis, from abscess formation.¹⁵¹

Osteomyelitis

Osteomyelitis about the hip is most commonly caused by hematogenous seeding; however, other sources of spread

include a contiguous soft tissue infection, direct implantation, such as from a puncture wound, or after surgery.¹⁷³ Although CT and MRI findings in osteomyelitis may be nonspecific, both modalities are sensitive indicators of infection of the marrow space in the appropriate clinical setting (Fig. 49–10).¹⁵¹

CT changes indicative of osteomyelitis are cortical destruction (particularly with osteomyelitis arising from contiguous spread), periosteal reaction, and increased attenuation within the marrow space.^{12, 74} Inflammation in the surrounding soft tissues is also often visualized on CT, seen as muscle and skin thickening, and soft tissue stranding in the subcutaneous fat.

MRI is superior to CT in identifying acute osteomyelitis, primarily because of its improved contrast resolution.^{16, 20, 74, 151} Acute osteomyelitis reveals replacement of fatty marrow with low to intermediate signal intensity on T1-weighted and with high signal intensity on T2-weighted images.^{63, 151, 200} These changes represent inflammatory and edematous tissue and usually demonstrate ill-defined margins with similar changes in the surrounding soft tissues.

The sensitivity of MRI in detecting osteomyelitis has been reported by Erdman and colleagues to be up to 98%; however, specificity was lower at 82%.⁶³ Both sensitivity and specificity of MRI are superior to those of CT and scintigraphy.^{61, 63, 74}

The degree of activity in sites of chronic osteomyelitis often creates a clinical dilemma. Identification of new bone destruction, as well as the presence of irregular periosteal reaction and *sequestra* (small sclerotic avascular bone fragments surrounded by granulation tissue), suggests active osteomyelitis. CT can be valuable in detecting these findings, particularly sequestra (Fig. 49–10B).^{12, 74} Although by definition sequestra are not infected, they provide an ideal milieu for organisms and must be considered foci of residual infection in the appropriate clinical setting. It is our belief that because of improved spatial resolution, CT is better to detect sequestra; overall, however, MRI may be superior to all other methods (including indium white blood cell scanning) in identifying active areas of osteomyelitis.¹³⁹

On T1-weighted MR images, marrow replacement is

Figure 49–10. The patient is a 13-year-old girl with a 1-year history of intermittent right hip pain, now worsening with fever and clinical signs of sepsis. The patient had a history of bladder infection caused by *Staphylococcus aureus* 1 year earlier.

A, Pelvic radiograph shows channel-like lucency (large arrows) with associated sclerosis (large arrowheads) in the proximal femur. B, CT shows a Brodie abscess (small arrowheads) with sequestra (small arrow). There is soft tissue thickening posteriorly, although focal fluid is not seen. C, Sagittal T1-weighted MR image reveals marrow replacement in the proximal femur (curved arrow) with a channel-like abscess (small arrowheads). D, Coronal T2-weighted MR image shows soft tissue changes of focal abscess (asterisk) and more diffuse edema (open arrows) posteromedially. The intraosseous abscess had extended into the soft tissues, causing the patient's acute symptoms. Both soft tissue and an intraosseous abscess were drained at surgery; culture revealed *S. aureus* as the causative organism. Soft tissue abscess was larger on a more posterior coronal T2-weighted MR image (not shown).

seen in chronic osteomyelitis because of fibrosis and osseous sclerosis regardless of the activity of the infection. On T2-weighted MR images, however, active foci of infection show high signal intensity.^{41, 43, 131, 137, 139, 200}

On T1-weighted and T2-weighted images, sequestra have low signal intensity; on long TR images, however, the surrounding inflammatory tissue shows a high-intensity halo. Subacute osteomyelitis, such as a Brodie abscess, can be identified on CT and MRI as a focal, intraosseous fluid collection, often lobulated or showing focal areas of elongation or channel-like extensions with surrounding sclerosis (Fig. 49–10B, C, and D).^{131, 137} The fluid may be complex and, compared with simple fluid, may have higher attenuation or signal intensity on T1-weighted MR images. The surrounding sclerosis has low signal intensity on all MR images.

Soft Tissue Infection

Soft tissue infection about the hips can involve the joint or surrounding muscles. In the appropriate clinical setting localized fluid collection usually requires fluid drainage for adequate treatment. CT and MRI are helpful because of their ability to identify anatomically localized fluid collections. CT and MRI changes suggesting an infected fluid collection are internal debris or septations and a thick wall (best seen on postcontrast images with enhancement).⁵⁰ The abscess wall often has intermediate signal intensity on T1-weighted images, perhaps as a result of increased protein content.

MRI, again because of its improved contrast resolution, is superior to CT in detecting fluid collections (see Fig. 49–10D). CT should be performed with IV contrast material when the possibility of an abscess is considered.^{12, 74} The absence of focal fluid collections by imaging essentially excludes localized soft tissue infection.

The location of the fluid collection about the hip determines the infected site: septic joint, bursitis, tenosynovitis, soft tissue abscess, or sinus tract or fistula (see Fig. 49–10D). Septic bacterial arthritis involving the hip joint is a surgical emergency (see earlier) because of the rapid cartilage destruction that can result.

Hip joint infection is common in infancy and childhood. CT and MRI show nonspecific joint fluid. MRI, in addition, can reveal early cartilage destruction indicative of infection. More indolent infections, including tuberculous and fungal forms, often result in a prominent synovitis, and the MRI appearance may simulate a noninfectious inflammatory arthritis. However, any case of monoarticular arthritis should be considered infectious until proved otherwise.

Osteomyelitis is frequently associated with septic arthritis of the hip because of both joint anatomy and cartilage loss, which expose underlying bone to infection. Tendons involved by infection reveal fluid within the sheath. This fluid surrounds the tendon, which has high attenuation on CT and low signal intensity on all MR pulse sequences. Soft tissue abscess may be superficial or deep focal fluid collections. Cellulitis has an appearance of inflammation or edema, with muscle and skin thickening and soft tissue stranding in the subcutaneous tissue on CT as well as diffuse heterogeneous linear high signal intensity seen on T2-weighted MR images.^{16, 20, 200}

CT and MRI allow distinction of the nonlocalized changes of cellulitis from the focal fluid collection of a soft tissue abscess (see Fig. 49–10D). This determination is vital to guide patient management because cellulitis is treated medically, whereas abscess is treated with drainage. MRI often reveals slightly higher signal intensity with T1-weighting about infected focal fluid collections (bone or soft tissue).

Sinus and fistula tracts are more common in adults and are seen as linear tracts on CT and MR images. On CT scans, these tracts have high-attenuation walls; on long TR images, high signal intensity often represents fluid in the tracts. Sinus tracts are not unusual sequelae of osteomyelitis of the ischial tuberosities in paraplegic patients with chronic decubitus ulcers (Fig. 49–11). These sinus tracts may seed the hip joints, causing septic arthritis, osteomyelitis, and joint destruction.

Trauma

Trauma about the hip is common. The two most frequent types of fractures involve the acetabulum and the proximal femoral neck.

Acetabular fractures and fracture dislocations are usually caused by motor vehicle accidents, and the complex anatomy and fracture patterns frequently require additional imaging beyond radiographs. Femoral neck fractures are often easily diagnosed on radiographs, although some injuries are quite subtle, requiring additional imaging.

Acetabular Fractures

Acetabular fractures constitute between 20% and 25% of all pelvic fractures in adults.¹⁸⁸ These fractures have a high association with concomitant injuries to the genitourinary system and vascular structures. Radiographs with oblique (Judet) views are often difficult to evaluate in determining the extent of involvement for presurgical planning.^{97, 124}

CT is the modality of choice for evaluation of these injuries.^{78, 82} Axial images should be performed with contiguous slices not thicker than 3 mm. Sagittal and coronal reconstructions and three-dimensional (3D) images are often helpful for the radiologist, and—more importantly—for the orthopedic surgeon, to conceptualize the fracture pattern before surgery.^{52, 67, 124, 138, 181}

The normal acetabulum is formed by two columns, one anterior (iliopubic) and the other posterior (ilioischial); these unite superiorly in the shape of an inverted Y. Medially, the bone between the anterior and posterior columns is the quadrilateral plate, and the acetabular socket is completed superiorly by the weight-bearing surface, called the roof.¹⁹¹ Acetabular fractures can be divided into five basic or elementary patterns:

- Posterior wall
- Posterior column
- Transverse
- Anterior column
- Anterior wall

Figure 49-11. The patient is a paraplegic 35-year-old man with chronic decubitus ulcers and fever. **A**, Pelvic radiograph shows bone destruction and production about the ischial tuberosities (*large arrowheads*) from chronic osteomyelitis and subcutaneous air related to the decubitus ulcers (*asterisks*). There is also chronic destruction of the right femoral head (*large arrows*). **B**, Coronal T1-weighted MR image reveals sinus tract (*small arrowheads*) extending from the ischial area of osteomyelitis (*open arrow*) that seeded the right hip joint, resulting in an additional site of pyarthrosis and osteomyelitis (*curved arrow*). **C**, CT scan shows bone destruction about the right hip (*curved arrow*). A large fluid collection anteriorly represents abscess (*small arrows*) and subcutaneous air (*asterisk*).

In addition, complex fractures occur with various combinations of the elementary components.^{97, 159, 188}

Posterior column or posterior wall fractures account for nearly 30% of all acetabular fractures.¹⁷⁴ These fractures are most common and are often a result of posterior hip dislocation (Fig. 49-12). The extent of posterior wall defect is well evaluated on CT and is important in determining both hip stability after reduction and the need for operative fixation.

Posterior dislocation is the most common type of hip dislocation (85% to 90% of cases) (see Fig. 49-12).¹⁷⁴ CT allows identification of associated intra-articular fragments (see Fig. 49-12) and impaction fractures or shearing osteochondral fractures of the femoral head, which are common sequelae of this injury.^{174, 202} Impaction fractures (seen in 13% to 61% of posterior hip dislocations) involve the anterior surface of the femoral head and are due to compression of the femur on the posterior acetabulum during dislocation. Large portions of the femoral head can be sheared (seen in 7% to 10% of posterior hip dislocations) from the remainder of the femur during dislocation (Fig. 49-13). These can be difficult to detect on radiographs, and CT is helpful in directing surgical fixation.

Fairbairn and colleagues have described focal areas of

Figure 49-12. Posterior column fracture with dislocation in a 30-year-old man after a motor vehicle accident. CT scan shows the femoral head posteriorly dislocated (*large arrowheads*), with small intra-articular fragment (*small arrowhead*), fractured posterior column (*large arrows*), and lipohemarthrosis in the joint (*open arrows*).

Figure 49-13. Shearing femoral head osteochondral fracture resulting from posterior hip dislocation in a 39-year-old man after a motor vehicle accident. *A*, Pelvic radiograph after reduction shows a small fragment superolateral to the left hip (*large arrow*); however, large osteochondral femoral head fragment is only vaguely visible (*large arrowheads*). *B*, CT at the lower extent of the acetabulum shows a large osteochondral femoral head fragment (*small arrowheads*) that is rotated 180 degrees, with its articular surface facing the remainder of the femur. The posterior column of the acetabulum is largely intact (*small arrows*). Subcutaneous air is seen anteriorly from associated soft tissue injury.

air in the hip joint as a sign of posterior hip dislocation (even if spontaneous or surgically reduced) resulting from *vacuum phenomenon* within the joint.⁶⁵ This finding should emphasize the need to search for associated osteochondral fragments in the joint arising from the femoral head or acetabulum.

Posterior column fractures are associated with central dislocations, and the fracture is directed obliquely across the posterior inferior acetabular fossa and inferior pubic ramus. This type of fracture separates the posterior column from the remainder of the iliac bone.

Transverse fractures (8% to 10% of acetabular fractures) are axially oriented injuries involving both columns (Fig. 49-14).^{188, 191} These fractures separate the innominate bone into superior and inferior fragments, usually at the level of the acetabular roof. They are often associated with central fracture dislocations.

Anterior column and anterior wall fractures account for only 6% to 7% of acetabular fractures and may be associ-

ated with anterior hip dislocation.^{188, 191} Analogous to posterior column fractures, anterior column injuries divide this area from the remainder of the innominate bone. Anterior wall fractures only involve a portion of the anterior column. Anterior hip dislocations account for 10% to 15% of all hip dislocations.^{188, 191} Associated impaction fractures of the femoral head are not uncommon and may be detected only on CT as a cortical indentation along the posterolateral femoral head.

Complex acetabular fractures combining two or more elementary fracture components are common. Frequently observed patterns combining two or more elementary components include transverse and posterior wall fractures (associated with posterior and central hip dislocation), fractures of both columns, and T-shaped fractures.^{78, 82, 188, 191} The T-shaped injury combines a transverse fracture with a vertical component usually extending into and dividing the obturator ring.

CT, in addition to initially evaluating acetabular fractures, can be used to assess both the adequacy of reduction after fixation and the position of metallic devices (particularly to exclude intra-articular location).¹³ Some artifact is produced by the orthopedic fixation; however, these devices are relatively small in the acetabulum, and the use of bone windows and reconstructions usually allows adequate evaluation by CT.

Figure 49-14. The patient is a 25-year-old man who sustained a transverse acetabular fracture in an automobile accident. Sagittal CT reconstruction shows the axially oriented fracture (*arrows*) involving both columns at the level of the acetabular roof, dividing the innominate bone into superior and inferior fragments.

Femoral Neck Fractures

Femoral neck fractures are common, with more than 250,000 subcapital fractures occurring annually in the United States at a cost exceeding \$9 billion in direct medical and indirect morbidity expenses.¹⁸⁶ Most of these fractures are well evaluated with radiographs. With the relatively recent advent of MRI, however, occult femoral neck fractures have become more often reported in older patients. Scintigraphic results may be falsely negative in these older osteoporotic patients for up to 4 or 5 days.¹²⁶

MRI can be helpful in these patients, and only coronal T1-weighted images are needed to detect an abnormality.

If the marrow signal is normal, a fracture is immediately excluded. Fractures often have a linear or bandlike oblique or horizontal marrow replacement pattern seen on T1-weighted images (Fig. 49-15A).^{19, 167} On T2-weighted or inversion recovery MR images, areas around the fracture line show increased intensity caused by hemorrhage and edema; however, the fracture line often retains low signal intensity (Fig. 49-15B).^{175, 230} This low signal intensity on long TR images may not be apparent in all cases, particularly before callus formation begins.

On MR images, *stress fractures* have a similar appearance; these are frequent in the pubic rami and supra-acetabular region in older patients (insufficiency fracture)

and in the medial femoral neck in young patients (fatigue fracture).¹²²

Subchondral fractures of the femoral head have been reported with a linear band of low signal intensity on T1-weighted MR images simulating avascular necrosis (AVN).²²⁹ Pubic rami and femoral neck insufficiency fractures (normal stress on bone of deficient elastic resistance) in elderly patients with osteoporosis occasionally simulate pathologic fractures. This is caused by post-traumatic osteolysis simulating an osteolytic lesion or callus formation, subacutely suggesting a chondroid- or osteoid-producing neoplasm.¹⁷³ This appearance can be particularly confusing when previous radiographs, at the time of the acute fracture, are not available for review. In these cases, CT is often useful to define the linear fracture plane and sur-

Figure 49-15. Occult femoral neck fracture in a middle-aged woman with hip pain. A, Coronal T1-weighted MR image shows a linear band of low intensity in the basicervical region of the right femoral neck (*arrows*) representing the fracture with surrounding marrow replacement from edema and hemorrhage (*arrowheads*). B, Coronal T2-weighted MR image shows a linear low signal intensity band representing the fracture line (*arrows*) and surrounding high signal intensity resulting from marrow edema (*arrowheads*). A radiograph (not shown) revealed vague sclerosis in this area of the femoral neck, retrospectively. (Courtesy of Harold Campbell, M.D.)

Figure 49-16. Pubic insufficiency fracture simulating a neoplasm in a 61-year-old woman. *A*, Pelvic radiograph shows changes in the symphysis on the left with sclerosis, suggesting a chondroid- or osteoid-producing lesion (*arrows*). *B*, CT reveals linear fracture plane and surrounding callus (*arrowheads*) resulting from the healing fracture and no evidence of a soft tissue mass.

rounding callus and to confirm no evidence of soft tissue mass (although muscle thickening may be present) (Fig. 49-16). These factors exclude neoplastic involvement as a reasonable consideration.

MRI can also be used to evaluate muscle tears and hemorrhage about the hip⁵⁴; these most frequently involve the rectus femoris muscle anteriorly and the hamstrings posteriorly. In 1999, tears of the abductor muscle's attachment to the greater trochanter (rotator cuff tear of the hip) were described.¹⁰²

The appearance of intramuscular hemorrhage is somewhat inconsistent; however, the most characteristic pattern is increased signal intensity on T1-weighted and T2-weighted images, with the area of involvement being much larger on long TR images (see Fig. 49-9A and B).^{54, 179, 225} Chronically low-signal-intensity areas on all pulse sequences may be apparent because of hemosiderin and fibrosis. The area involved on MR images is frequently irregular and infiltrative, representing blood dissecting between muscle bundles, and surrounds the low-signal-intensity intramuscular component of the tendon. The multiplanar imaging capability of MRI is also helpful in assessing the degree of muscle disruption and in directing intervention when tears are complete.

Neoplasia

Neoplastic involvement about the hip, both benign and malignant, can involve either the osseous structures or soft tissues. CT and MRI can provide localization and characterization of these neoplastic lesions, factors that are invaluable in staging and preoperative planning. Advantages of MRI include (1) multiplanar imaging, (2) superior contrast resolution, and (3) lack of ionizing radiation.

Although MRI has supplanted CT as the modality of choice in evaluation of many musculoskeletal masses, CT can still play an important role. Osseous neoplasms that produce mineralized matrix not adequately assessed on radiographs are often better evaluated by CT.^{201, 222} CT allows improved detection and characterization of the ma-

trix, particularly important when this is subtle, to determine whether the lesion is of osteoid or chondroid derivation.

Numerous primary osseous neoplasms occur about the hip; however, commonly encountered lesions include (1) osteoid osteoma, (2) chondroblastoma, and (3) chondrosarcoma.

Symptoms usually include nonspecific pain. Radiography should be the initial imaging in any case of suspected osseous neoplasms. The radiographs are of primary importance to identify the lesion, to characterize its margin and aggressiveness, to detect any mineralized matrix formation, and to provide a reasonable differential diagnosis. CT, MRI, or both may then be performed to further characterize the lesion and to delineate its extent.

Osteoid Osteoma

Osteoid osteoma is common, accounting for 10% to 12% of primary benign skeletal neoplasms.^{104, 110} These lesions are seldom larger than 1.5 to 2.0 cm in diameter and are classified by their location as (1) *cortical* (75%), (2) *cancellous* (25%), or (3) *subperiosteal* (rare).

Cortical lesions are the most common type in long bones, such as the tibia and femur, and are usually easily identified as a small, radiolucent nidus with extensive surrounding reactive sclerosis and cortical thickening.

Cancellous lesions are most common about the hip, with the proximal femur involved more frequently than the acetabulum. These lesions are often difficult to detect on radiographs because of their small size and lack of prominent reactive sclerosis resulting from limited periosteal tissue in the region.³⁸

Patients' clinical findings may suggest inflammatory synovitis, and the classic history of night pain relieved by aspirin may not be apparent. Patients are usually between 10 and 20 years of age, and males are affected about two to three times as frequently as females.^{104, 110} Radiographs of the hip may be nonspecific, showing only disuse osteopenia. Periosteal reaction may be seen only inferior to

Figure 49-17. Intra-articular osteoid osteoma in a 16-year-old boy with hip and knee pain. *A*, CT scan shows a focal low-attenuation nidus (small arrowheads) in the endosteal region of the femoral neck medially with mild associated reactive sclerosis (arrows). *B*, Proton-density axial MR image reveals osteoid osteoma nidus of intermediate intensity (small arrowheads) with reactive sclerosis showing low signal intensity (arrows). Reactive joint effusion resulting from lymphofollicular synovitis is also seen (large arrowheads).

the joint capsule attachment, in the subtrochanteric region.⁷⁷

Because of these difficulties, CT is often valuable in identifying these lesions and is usually preferable to MRI. On CT scans, the nidus is a well-defined area of decreased attenuation with a variable degree of surrounding reactive sclerosis (Fig. 49-17A). The nidus, which is composed of osteoid and woven bone, may show mineralization on CT in approximately 50% of cases.^{92, 104, 184} This mineralization is usually a solitary central focus within the nidus but may be ringlike or multifocal; rarely, the entire nidus is ossified.

MRI is usually not necessary to detect these lesions, and the appearance has been reported to be quite variable, depending on the degree of mineralization. The nidus may show low to intermediate signal intensity on T2-weighted images if it is mineralized, or its signal intensity may be similar to that of fat or higher if it is nonmineralized (Fig. 49-17B).^{92, 104, 110} This situation can create a target appearance, with the low-signal-intensity rim representing sclerosis. On long TR images, extensive marrow edema surrounding the nidus may obscure the lesion.

Both CT and MRI may show an associated joint effusion resulting from a lymphofollicular synovitis as well as contrast enhancement from the vascular nidus (see Fig. 49-17B). A reactive soft tissue mass with osteoid osteoma has been reported on MR images,^{22, 227} although this should not be surprising or confused with a more aggressive process. It represents another manifestation of associated inflammatory response seen with these lesions, as opposed to a true “mass.” CT is invaluable for localizing the nidus for the orthopedic surgeon before open resection and can also be used to direct needle placement before surgical removal.^{105, 194} In addition, CT can be used to treat osteoid osteoma by guiding core needle or electrode placement for percutaneous removal (Fig. 49-18) or radiofrequency ablation, respectively, while the patient is on the CT table.^{10, 57, 141, 177}

Chondroblastoma

Chondroblastoma, a benign chondroid neoplasm, involves primarily the epiphysis of young patients between

10 and 20 years of age.¹⁴⁰ One of the most common sites, the proximal femur, is involved in 16% of cases; less frequently involved is the iliac bone, in the area of the triradiate cartilage.^{27, 140} The lesion is usually seen on radiographs as a radiolucency within the epiphysis eccentrically (Fig. 49-19A) that may extend into the metaphysis (55% of cases).¹⁷³ There is usually a rim of surrounding sclerosis.

Thick periosteal reaction may be seen in 50% of patients with proximal femoral lesions.³² The periosteal reaction is distal to the lesion about the femoral neck and subtrochanteric region (see Fig. 49-19A). The differential diagnosis of epiphyseal lesions in the proximal femur includes Langhans cell histiocytosis and infection.

CT can be helpful in detecting distinctive chondroid calcification (a ring and arc appearance), which is present in up to 60% of cases of chondroblastoma and which can be difficult to identify on radiographs (Fig. 49-19B).²⁷ On T1-weighted images, MRI shows marrow replacement. In our experience, most chondroblastomas retain low to intermediate signal intensity on long TR images (solid components), a feature that is unusual for most osseous neoplasms, particularly cartilage tumors (Fig. 49-19C and D). This MRI appearance is probably related to high cellularity, fibrosis, or areas of chondroid mineralization. Cystic (aneurysmal bone cyst) elements may also be seen. As with osteoid osteomas, MRI may show hip joint effusion and extensive surrounding edema with chondroblastoma (see Fig. 49-19C and D).

Many different primary and metastatic osseous malignancies occur about the hip. Multiple myeloma and metastatic foci are well evaluated by MRI and typically show marrow replacement on T1-weighted images and high signal intensity on long TR images (Fig. 49-20).^{168, 170} Myelomatous areas of involvement, diffuse or focal, occasionally retain low signal intensity on T2-weighted MR images (see Fig. 49-20).^{75, 129, 152, 173, 204} Osteoblastic metastases often show significant areas of low signal intensity corresponding to the sclerosis on T2-weighted images and high attenuation on CT scans. The size, extent, and presence of associated soft tissue mass are well evaluated on MRI; this information can be important in patient management.

Figure 49-18. The patient is a 22-year-old man who underwent percutaneous removal of a proximal femur cortical osteoid osteoma under general anesthesia. CT scan shows initial localizing needle placement (A) directed toward the low-attenuation nidus (arrowhead). Marked reactive cortical thickening is present (arrows). Craig needle apparatus was then used to remove a core of bone, including the nidus. The core tract (B) is seen (arrowheads) with removal of the low-attenuation nidus. The patient was discharged from the hospital within 23 hours of this procedure.

Figure 49-19. Chondroblastoma of the right femoral head in a 14-year-old boy after several months of hip pain. A, Pelvic radiograph shows deformity of the right femoral head with a periosteal reaction in the medial femoral neck (open arrow). The lytic lesion (curved arrow) is difficult to detect. B, CT scan reveals the lytic lesion (small arrowheads) with surrounding sclerosis and chondroid matrix within the chondroblastoma (arrows). Joint effusion is also identified (large arrowheads). C, Coronal T1-weighted MR image reveals diffuse marrow replacement in the right proximal femur (asterisks) with the chondroblastoma difficult to distinguish as a focal lesion. Periosteal reaction is seen as increased signal intensity within the medial femoral neck cortex (open arrow). D, Coronal T2-weighted MR image shows diffuse, mildly increased marrow signal intensity in the right femur from edema (asterisk). The chondroblastoma shows low signal intensity (small arrowheads) resulting from chondroid matrix and high cellularity (confirmed by pathologic examination). Associated high-signal-intensity joint effusion (large arrowheads) and periosteal reaction (open arrow) are also seen.

Figure 49–20. Multiple myeloma involvement of the proximal femoral heads in a 65-year-old woman. Coronal T1-weighted (A) and T2-weighted (B) MR images reveal multiple focal areas of marrow replacement (*arrowheads*) resulting from myelomatous involvement. In B, most of these lesions retain low signal intensity, although in the right femur the largest lesion shows mild increased intensity (*arrows*). The size of this lesion suggests impending pathologic fracture, and the right femur was prophylactically internally fixed with an intramedullary rod.

CT shows myeloma and lytic metastatic lesions as areas of higher attenuation replacing the normally fatty marrow space, and the degree of cortical involvement is easily assessed. CT and MRI are helpful in evaluating metastatic and myelomatous lesions to determine impending pathologic fracture of the proximal femur (a high risk if the lesion is larger than 2 to 3 cm in size, if greater than 50% of the cortex is involved or if the patient has postradiation pain) and to guide the need for prophylactic fixation and radiation therapy (see Fig. 49–20).^{75, 192}

Chondrosarcoma

Chondrosarcoma is one of the more frequently occurring primary bone malignancies to involve the osseous structures about the hip. Approximately 25% of all chondrosarcomas involve the pelvis, with many occurring about the proximal femur (particularly the clear cell variety) and acetabulum in the region of the triradiate cartilage (Fig. 49–21).^{165, 173}

CT is effective in identifying and characterizing the chondroid matrix, which appears as rings and arcs of calcification, when radiographs are not adequate because of lack of contrast resolution or complex pelvic anatomy (Fig. 49–21B).^{8, 45, 170} CT also allows identification of any soft tissue mass, which is common in higher-grade chondrosarcomas (up to 50% of cases).^{173, 218}

MRI is superior to CT in demonstrating the extent of marrow and soft tissue involvement in chondrosarcoma or other osseous neoplasms about the hip. Marrow replacement is as seen on T1-weighted images, and relative high intensity is seen on T2-weighted images. Mineralization is of low signal intensity on all pulse sequences; however, it is not as well characterized by MRI as by CT.²¹⁸ The multiplanar imaging capability of MRI is important in assessing osseous neoplasms about the hip for surgical planning. Detection of hip joint invasion is particularly important because resection of structures on both sides of the joint is then required. Involvement of the joint is

usually best shown on coronal and sagittal images with soft tissue mass within the articulation and with associated effusion (Fig. 49–21C and D). In our experience, the absence of a joint effusion in cases of osseous malignancy about the hip essentially excludes joint involvement.

Soft tissue masses about the hip, both benign and malignant, are not uncommon.^{62, 109} MRI has largely supplanted CT as the modality of choice in evaluation of these masses.^{192, 196, 201, 221, 222} A specific histologic diagnosis by MRI is apparent in only approximately 25% to 40% of cases (lipoma, hemangioma); however, the contrast resolution of MRI allows exquisite distinction of tumor from surrounding soft tissue and osseous structures.^{109, 132} Staging of soft tissue neoplasm for presurgical planning is also aided by the multiplanar imaging capability of MRI.^{192, 196}

MRI is also important in assessing the effects of chemotherapy and radiation therapy on tumor size and extent, for both osseous and soft tissue components of musculoskeletal neoplasms.^{64, 212, 213} In general, a decreased intensity on T1-weighted images and an increased intensity on long TR images suggest a response to therapy with necrosis and edema. MRI is also vital in postoperative evaluation to detect early soft tissue recurrence. Edema resulting from surgery and radiation results in irregular, nonlocalized, often linear areas of high signal intensity on long TR images that do not disrupt the normal muscle texture pattern on T1-weighted images.^{23, 212, 213} However, any nodular regions not characteristic of fluid (seroma or lymphocele) that disrupt the muscle texture on T1-weighted images should be considered residual or recurrent tumor.²³ Recurrent osseous neoplasm is seen as new areas of marrow replacement.

After IV injection of gadolinium, MRI is useful for distinguishing vascular tissue (neoplasm, granulation tissue, inflammation) from nonvascular components (hemorrhage, necrosis, seroma, lymphocele, abscess) following surgery.^{64, 212} By using dynamic contrast-enhanced subtraction MRI, Vanel and coworkers have suggested that tumor recurrence can be distinguished from other tissues.²¹³ Neoplastic tissue shows enhancement in the early stages (the

Figure 49-21. Chondrosarcoma of the left acetabulum in a 30-year-old man with vague hip pain of several months' duration. *A*, Radiograph of the pelvis shows subtle aggressive bone destruction of the medial left acetabulum with permeation of the iliopectineal line (curved arrows). *B*, CT scans show bone destruction with chondroid matrix formation (large arrowheads) and an associated soft tissue mass (asterisk). *C* and *D*, Coronal T1-weighted MR image (*C*) and axial T2-weighted MR images (*D*) reveal marrow replacement (small arrowheads) and soft tissue mass (asterisk), which becomes high signal intensity on the long TR/TE image (*D*). The soft tissue mass has invaded the hip joint, as evidenced by the fact that the soft mass abuts the femoral head (arrows).

first 2 minutes), in contrast to non-neoplastic tissue, which enhances at a later time.²¹³

Avascular Necrosis and Transient Osteoporosis

Avascular Necrosis

Osteonecrosis of the hip is caused by an insufficient vascular supply to the femoral head. AVN of the femoral head results from numerous abnormalities, including trauma, steroids, collagen vascular disease, alcoholism, pancreatitis, hemoglobinopathies, and Gaucher disease.^{39, 70, 173} AVN may also be idiopathic in both adults and children (Legg-Calvé-Perthes disease). Trauma is the most frequent known cause of AVN, usually related to femoral neck fracture or hip dislocation, with an increasing incidence associated with the degree of displacement and delay in reduction.⁷⁰ AVN related to trauma is usually unilateral, whereas nontraumatic osteonecrosis is bilateral in up to 70% of patients.⁷⁰

The common sequelae of AVN are collapse and joint deformity with subsequent osteoarthritis and pain; these often lead to orthopedic intervention and account for 10% of all total joint replacements in the United States.⁷⁰ Numerous treatment modalities are available, including a variety of joint replacements, joint fusion, or joint-preserving surgery such as core decompression or osteotomy. The use and success of core decompression, which reduces the intramedullary pressure thought to be the underlying cause of AVN, are controversial in the orthopedic literature.^{17, 43} However, most experts agree that this procedure, if used, must be performed at the earliest stages of AVN to be of significant benefit.

Various staging systems have been used to assess femoral head AVN. The most commonly used classification is that developed by Ficat and Arlet.⁹ This system is based on radiographs:

Stage 0 disease. Patients are asymptomatic, as shown by normal radiographs and bone scan; only biopsy reveals changes of AVN.

Stage 1 disease. Patients have pain, a decreased range of motion, an abnormal bone scan, and a normal radiographic appearance.

Stage 2 disease. Radiographs show femoral head osteoporosis with areas of cystic lucency and sclerosis.

Stage 3 disease. There is progression to subchondral collapse (*crescent sign*).

Stage 4 disease. There is progressive segmental femoral head collapse with a normal hip joint space and acetabulum.

Stage 5 disease. Secondary osteoarthritic changes are seen on both the femoral and acetabular sides of the joint with narrowing.

MRI is clearly the most sensitive and specific radiologic modality available for detecting the early changes of AVN of the femoral head.^{31, 42, 71, 73, 203} The sensitivity of MRI in detecting AVN in symptomatic patients has ranged from 88% to 100% in studies of Markisz and Beltran and their coworkers^{17, 136}; sensitivity was 10% to 20% more than with bone scintigraphy. However, there is some delay between the histologic changes and development of MRI abnormalities of AVN; the extent of this gap remains unclear.^{71, 73, 199, 203} In animal studies, changes have been seen as early as 1 week.

On MR images, the typical marrow pattern seen with AVN is variably sized areas of decreased intensity on T1-weighted images, usually in the anterosuperior subchondral aspect of the femoral head laterally (Figs. 49-22 and 49-23). This area may be homogeneous or heterogeneous with band, ring, wedge, or crescentic configuration and regions of higher signal intensity centrally.²⁰⁷ In the study by Mitchell and coworkers,¹⁴⁹ this defect was present in 96% of patients, with the rim remaining low intensity on both T1-

Figure 49-22. Avascular necrosis (AVN) of both femoral heads in a 41-year-old patient receiving steroids for long-standing systemic lupus erythematosus. **A**, Coronal T1-weighted MR image shows focal crescentic areas of decreased marrow signal typical of AVN in both femoral heads (*arrowheads*). **B**, Coronal T2-weighted MR image shows linear high signal intensity band (*small arrows*) with a persistent low-signal-intensity rim (*large arrows*), consistent with the *double line sign*, characteristic of AVN on the right. The area of AVN on the left has fat-like signal intensity typical of class A changes, and predominantly low signal intensity on the right (fibrous tissue), typical of class D changes.

Figure 49-23. Legg-Calvé-Perthes disease in a 7-year-old boy with recent onset of right hip pain. Pelvic radiographs (not shown) were normal. **A**, Coronal T1-weighted MR image shows bandlike areas of marrow replacement in the superolateral aspect of the right femoral head (*small arrowheads*). Overlying cartilage (*large arrowheads*) appears intact, and the femoral head is well covered by the acetabulum. **B**, Coronal T2-weighted image reveals the areas of avascular necrosis to be largely high signal intensity (*small arrows*), consistent with class C changes (fluid-like). Minimal associated joint effusion is also present (*large arrows*).

weighted images (94% of cases) and long TR/TE sequences (86% of cases) (see Fig. 49-22).

The appearance of AVN on long TR/TE MR images is more variable but often adds specificity. A high-signal-intensity line within the low-intensity rim (*double line sign*) has been described in 80% of patients with AVN in one series (Fig. 49-22B).¹⁰⁸⁻¹¹⁰

Mitchell and coworkers have developed an MRI classification scheme based on the appearance of the central region.¹⁴⁷⁻¹⁴⁹ This area may simulate the following:

1. *Fat, class A.* High signal intensity on short TR/TE images, and intermediate signal intensity on T2-weighted images (see Fig. 49-22).
2. *Blood, class B.* High signal intensity on short and long TR/TE images.
3. *Fluid, class C.* Low signal intensity on short TR/TE images and high signal intensity on long TR/TE images (see Fig. 49-23).
4. *Fibrous tissue, class D.* Low signal intensity on all images (see Fig. 49-22).

Class A and B changes appear to correspond to early stages 1 and 2 of AVN, whereas class C and D changes correlate with the later stages of 3 and 4.¹⁴⁷⁻¹⁴⁹ In addition, clinical symptoms are usually most severe with class D changes and least prominent with class A findings.

MRI findings correspond to the histologic changes seen with AVN. Areas of low signal intensity on all sequences correspond to fibrosis or sclerosis, whereas regions of low signal intensity on short TR/TE images that become high signal intensity on long TR/TE images represent granulation tissue attempting to repair avascular regions. Marrow with residual high signal intensity on short TR/TE images represents necrotic tissue that is not invaded by granulation tissue.

The manifestations of AVN are usually best evaluated on coronal MR images; however, sagittal and axial sequences can be helpful in assessing regions of collapse.⁹⁰

MRI may also be useful in the assessment of patients with AVN after core decompression to evaluate for revascularization, further collapse, and any change in the volume of tissue involved.^{18, 154, 195, 206, 215}

It is vital to emphasize that long-term symptoms of AVN are related to collapse and the ensuing mechanical alterations. If collapse does not occur or if it is minimal, clinical symptoms are also typically not substantial, reflecting the fact that "dead bone is as strong as live bone." It is therefore important to identify radiologic features that are correlated to AVN that is more likely to lead to collapse and, perhaps, to provide earlier and more aggressive treatment for these patients.

Iida and colleagues suggested that the presence of bone marrow edema is a significant marker (85% of their 13 patients had this finding) for potential progression.⁹⁰ An additional feature increasing the likelihood of subsequent collapse is the volume of femoral head affected by AVN. Specifically, involvement of more than 25% of the femoral head diameter (and at least 67% of weight-bearing area) was associated with collapse by 32 months in the study by Shimizu and associates.¹⁹⁰

MRI findings of AVN may occasionally be nonspecific and may show only diffuse marrow edema without focal defects, as described in six patients by Turner and colleagues.²⁰⁸ This pattern can also be seen with transient osteoporosis of the hip. Use of IV contrast medium may help in this distinction and in earlier recognition of AVN. Areas of contrast enhancement are seen in regions of viable marrow and granulation tissue, whereas avascular regions lack enhancement.^{128, 207} Additional associated MRI features of AVN are small hip joint effusion and premature conversion of hematopoietic marrow to fatty marrow. This premature conversion was seen in more than 60% of patients with AVN in the study by Mitchell and coworkers and may be caused by ischemia.¹⁴⁷

MR images of Legg-Calvé-Perthes disease show identical changes as in other causes of AVN (see Fig. 49-23).

The capital femoral epiphysis often reveals necrosis centrally, with peripheral portions of viable epiphysis.^{60, 61} Peripheral portions of viable epiphysis may also develop or may increase in size with revascularization and healing.^{60, 187} This is important in treatment because viability of the lateral aspect of the epiphysis corresponds to a reduced risk of further deformity or to an extension of AVN.¹⁸⁷ In these patients, bracing can be discontinued and the patient can begin weight bearing.

MRI can also assess the shape of the cartilaginous portions of the femoral head and the degree of containment by the acetabulum. Dynamic MRI has now been used on open configuration MRI units to assess containment and to detect hinge abduction (blocking of a flattened femoral head against the lateral acetabulum). These determinations are vital in identifying children who require treatment by an osteotomy (25% of patients). Previously, this information had to be obtained by arthrography.⁶⁰

CT is less sensitive than MRI in detecting AVN. The earliest CT sign of AVN is alteration of the asterisk, a starlike condensation of trabeculae in the normal femoral head.⁵³ Changes in the asterisk in early AVN have been described as central or peripheral clumping or sclerosis (Fig. 49–24). CT is probably superior to MRI in evaluation of long-standing AVN to delineate structural deformities of the femoral head, such as subchondral fracture, collapse, and calcified intra-articular fragments. When osteotomy is planned as a temporizing procedure, CT is often useful in determining which femoral surface is best preserved.^{134, 135, 183} This information guides the surgeon in determining the feasibility and type of osteotomy to perform.¹³⁵

Transient Osteoporosis

Transient osteoporosis of the hip, as originally described in women, almost exclusively involved the left hip in the third trimester of pregnancy.^{61, 173, 228} It is now recognized

Figure 49–24. Bilateral avascular necrosis (AVN) of the femoral heads in a 22-year-old man receiving steroid therapy for Crohn disease. CT scan shows focal sclerosis in both femoral heads posteriorly (arrows), typical of AVN with minimal cortical collapse (arrowhead) on the left.

as actually being more common in middle-aged men and affecting either hip. Symptoms include severe hip pain and decreased range of motion that resolves spontaneously in 6 to 12 months.²¹⁴

The etiology is poorly understood, and the disease has been associated with a type of reflex sympathetic dystrophy syndrome. It may be migratory, with subsequent involvement of the opposite hip or an adjacent joint. Radiologic changes may simulate indolent infection, osteonecrosis, or infiltrative neoplasm. The underlying pathologic condition appears to be bone marrow reaction or edema.^{58, 79, 163, 228} Current terminology may refer to this entity as *transient bone marrow edema syndrome*.²²³

Radiographs usually show osteopenia, and bone scan reveals intense activity focally within the femoral head—unlike AVN, which often displays central photopenia.

MRI demonstrates diffuse marrow abnormalities that usually extend from the subchondral femoral head to the intertrochanteric and subtrochanteric regions. There is low signal intensity on T1-weighted MR images and high signal intensity on T2-weighted sequences (Fig. 49–25).^{3, 26, 84, 85, 164} These MRI changes reflect the nonspecific marrow reaction or edema that is present. Focal marrow defects in the subchondral region or subtle femoral head flattening should be searched for diligently on MR images; unlike the case with AVN, these defects are usually absent in transient osteoporosis.

In 1999, Vande Berg and coworkers described small subchondral areas of low signal intensity in 30% of patients with bone marrow edema syndrome.²¹⁴ Lesions that were less than 4 mm thick or 12.5 mm long (*reversible*) returned to normal as opposed to those that were larger (*irreversible*) that continued onto collapse, probably representing progression to AVN.²¹⁴ IV gadolinium injection may also be useful in these patients to help distinguish AVN from transient osteoporosis.^{89, 216}

In transient osteoporosis, diffuse, homogeneous enhancement of the marrow space and edema are seen on postinjection T1-weighted images to a greater extent than that seen in contralateral normal femoral marrow (Fig. 49–26). This is in contradistinction to AVN, in which contrast enhancement is heterogeneous, with avascular foci showing persistent low signal intensity resulting from lack of enhancement. According to Bloem,²⁶ MR images gradually improve in transient osteoporosis of the hip without residual defects in a 6- to 10-month time frame and return to normal marrow signal intensity (Fig. 49–25C).^{116, 118} These MRI findings lag behind clinical improvement.

Although the relationship between transient osteoporosis of the hip and AVN is unclear, some researchers now believe that the entities are related, with marrow reaction (increased fibrovascular tissue) being the important common pathologic feature.^{79, 163, 228} Transient osteoporosis of the hip might thus represent a *forme fruste* of AVN, with ischemia and resultant marrow reaction that, for some reason, does not progress to focal necrosis. Turner and colleagues have reported six patients with a bone marrow pattern seen on MRI without focal defects that showed AVN at biopsy.²⁰⁸ Studies with larger numbers of patients are required to further investigate the relationship between these two conditions. Recently, the importance of associ-

Figure 49-25. A–C, Transient osteoporosis of the hip in a 47-year-old woman with right hip pain of several months' duration. Pelvic radiograph and bone scan (not shown) revealed osteopenia of the right proximal femur and diffuse marked increased activity about the right femoral head, respectively. Coronal T1-weighted MR image (A) and T2-weighted MR image (B) show marrow replacement in the right femoral head and neck that becomes high signal intensity on the long TR image (asterisks), consistent with marrow edema. Three months later, symptoms resolved and the T1-weighted coronal MR image (C) shows a return to normal marrow signal intensity. No focal subchondral areas of marrow replacement were seen on any image to suggest avascular necrosis.

Figure 49-26. Transient osteoporosis of the hip in a 77-year-old man with a 3-month history of left hip pain. Coronal T1-weighted MR images before (A) and after (B) intravenous gadolinium injection show marrow replacement diffusely in the left femoral head and neck (asterisk), which enhances with contrast material to become isointense to normal marrow (asterisk), respectively. No focal nonenhancing areas are seen, as would be expected with avascular necrosis. Long-repetition-time (TR) MR images (not shown) revealed increased intensity in the left femoral head and neck, consistent with edema and small joint effusion. Patient symptoms and MRI changes resolved over the next 3 months without treatment.

ated subchondral fracture in transient osteoporosis of the hip has been suggested.¹⁵⁰

Summary

Joint pain is a frequent presenting clinical symptom for a variety of pathologic conditions that can involve the hip. Radiographs should be the initial radiologic study performed to assess these patients. Although radiographs may sometimes provide diagnostic information, in many instances further imaging is necessary. CT, and more recently MRI, are the radiologic modalities of choice to provide this additional assessment.

In this chapter, we have attempted to describe and illustrate the CT and MRI appearances of commonly encountered pathologic conditions of the hip. Recognition of these characteristics, as seen on CT scan and MR images, is important to provide our clinical colleagues with specific information that often allows diagnosis and directs patient management.

The Shoulder

Tamara Miner Haygood,
Kathleen Gallagher Oxner,
J. Bruce Kneeland, and Murray K. Dalinka

In 1993, when the first version of this chapter was drafted, hundreds of articles and one book²²⁰ had already been devoted to shoulder imaging. Since that time, published sources have increased greatly in number, with many new journal articles and another book.¹⁹⁰ Magnetic resonance (MR) arthrography, still a new technique of uncertain potential in 1993, has become accepted and is commonly performed in both academic and private practice settings. Orthopedists have revised their collective opinion of the cause and treatment of some shoulder disorders.

To accommodate this new material and yet confine the discussion to a reasonable length, disorders occurring in locations other than the shoulder are covered more succinctly than in our previous offering. Tumors, in fact, have been dropped entirely. SLAP (superior labrum, anterior and posterior) lesions are now included with other labral tears in the section on instability rather than separately. As we said last time, no scheme will please everyone, but we hope this arrangement will be satisfactory to most.

Anatomy

For purposes of this chapter, the shoulder is considered to include the glenohumeral joint, the acromioclavicular joint, and related soft tissues. The glenohumeral joint is relatively shallow, with the humeral head large in comparison to the glenoid fossa. This configuration grants mobility at the expense of stability. The labrum is a meniscus-like, fibrous or fibrocartilaginous structure that runs about the edge of the glenoid. It serves to increase the depth of the glenoid, providing more contact area and thus more stability for the glenohumeral joint. A recess lined with synovium may be interposed between the labrum and origin of the long head of the biceps brachii muscle. Anterior to this muscle origin and extending to the midglenoid, the labrum may be absent or unattached, with a smooth foramen between itself and the glenoid rim. A recess may also be present in this area.^{25, 95, 123, 157, 185, 197}

Surrounding the glenohumeral joint is the joint capsule, which attaches to both the anatomic neck of the humerus and the scapula. Its scapular attachment is variable, particularly at the midpoint of the glenoid. In this area, the capsule may attach to the anterior labrum, to the glenoid just medial to the labrum, or farther medially along the glenoid.^{123, 132}

Compared with the capsules of other joints, the glenohumeral joint capsule is relatively loose and allows maximal movement of the joint. There are three normal extensions of the joint capsule where joint fluid may be seen at

imaging in patients with an effusion. The first is a communication with the sheath of the long head of the biceps as it runs through the intertubercular groove. The second reaches under the coracoid process to communicate with the subscapular recess. The third is the axillary recess or axillary pouch, a loose fold of thickened capsule at the caudal extent of the joint that tightens when the arm is abducted. Normally, joint fluid is restricted to a thin film, with no distention of these recesses.^{121, 173}

Three glenohumeral ligaments are seen as thickened areas of the joint capsule:

1. The *superior* glenohumeral ligament arises from the superior glenoid within a centimeter anterior to the biceps origin and runs to the fovea capitis of the humerus. It is the most consistent of the three in its course and is often identified at cross-sectional imaging.^{26, 47, 147}
2. The *middle* glenohumeral ligament is the most variable of the three in its course and thickness. It often arises in common with the superior glenohumeral ligament and runs anteriorly in an inferolateral direction to the lesser tuberosity of the humerus.^{26, 47, 147}
3. The *inferior* glenohumeral ligament complex consists of distinct anterior and posterior bands separated by the axillary pouch. It runs from a broad-based origin along the mid to inferior labrum to the humeral neck. This complex is the most important ligamentous stabilizer, guarding against both anterior and posterior dislocations.^{142, 147}

A number of other ligaments also help stabilize the shoulder. The *coracoacromial* ligament passes deep to the deltoid and superficial to the subacromial-subdeltoid bursa. It supports the shoulder against upward pressure.¹²¹

The *coracohumeral* ligament runs from the lateral aspect of the base of the coracoid to insert on the humerus adjacent to the greater tuberosity, where its fibers blend at its insertion site with those of the joint capsule. It passively supports the humerus when the arm hangs at the side. It is also a major stabilizer of the biceps tendon in its groove.¹²¹

The *coracoclavicular* ligament is made up of two parts, the trapezoid ligament and the conoid ligament. The former runs from the coracoid process to the undersurface of the distal clavicle, and the latter runs from the coracoid to the more medially located conoid tubercle of the clavicle.¹²¹

The *acromioclavicular* ligament strengthens the superior portion of the tight-fitting acromioclavicular joint capsule. Both it and the coracoclavicular ligament stabilize the acromioclavicular joint.^{121, 170}

Four muscles (supraspinatus, infraspinatus, teres minor,

subscapularis), together with their tendons, form the *rotator cuff*. All originate on the scapula and insert on the humerus. They are responsible for abduction and internal and external rotation of the glenohumeral joint. Of these muscles, the supraspinatus is the one injured most often. It arches superiorly over the humerus to insert superolaterally on the greater tuberosity. The infraspinatus and teres minor also insert on the greater tuberosity, each a little more inferiorly and posteriorly. The subscapularis has a broad origin on the anterior scapula and inserts with multiple tendon slips onto the lesser tuberosity.

The large deltoid muscle extends from a very broad origin on the distal clavicle and acromion to insert into the deltoid tubercle of the lateral aspect of the proximal humeral diaphysis. Occasionally, a proximal tendon slip of the deltoid arises from the undersurface of the clavicle or acromion, where it may mimic a spur. The deltoid muscle is external to the rotator cuff and is separated from it by the subacromial-subdeltoid bursa and its associated extracapsular fat pad. The subacromial-subdeltoid bursa does not normally communicate with the glenohumeral joint. The peribursal fat pad has a rather variable appearance. At MRI, part of this fat pad may not be visible, either in normal shoulders or in shoulders with rotator cuff pathology.^{33, 82, 118, 133} The subcoracoid bursa lies caudal to the coracoid process and anterior to the subscapularis muscle. It communicates with the subacromial-subdeltoid bursa about half the time.¹⁷²

Between the greater and lesser tuberosities lies the bicipital groove, also called the intertubercular sulcus. This depression cradles the tendon of the long head of the biceps brachii, which originates from the superior glenoid tubercle and superior labrum. Its proximal tendon passes anteriorly over the humeral head through the rotator interval, a ligament-cloaked space separating the supraspinatus and subscapularis muscles. It then passes through the bicipital groove to the muscle belly. The tendon is secured in its groove superiorly by the coracohumeral ligament, its most important stabilizer, and by the transverse humeral ligament, to which the subscapularis tendon may lend some fibers. More distally, the tendon of the pectoralis major also contributes to stabilization of the biceps tendon in its groove.⁴¹

The coracoacromial ligament forms part of the coracoacromial arch, which consists of the coracoacromial ligament and the structures it connects—the coracoid process of the scapula and the anterior acromion. This relatively immobile complex not only provides support to the shoulder but may also impinge on the tendon of the supraspinatus muscle, causing tendinitis and contributing to an eventual tear.

Three different configurations of the acromion have been described. *Type I* is flat inferiorly. *Type II* curves smoothly. In *type III*, the most anterior portion of the acromion has a hooked shape.⁹ The acromion may also be convex along its inferior surface.⁴⁶ The inferior margins of the acromion and distal clavicle usually lie at approximately the same level in the coronal plane.

Three neurovascular structures are important to the imaging anatomy of the shoulder. Running on the posterior aspect of the scapula are the suprascapular nerve and artery. The nerve arises from the upper trunk of the brachial

plexus (C5 and C6) and passes through the suprascapular notch. It then runs deep to the supraspinatus muscle. When it emerges from beneath the supraspinatus muscle, it passes through the spinoglenoid notch. It carries both sensory and motor fibers and supplies motor innervation to the supraspinatus and infraspinatus muscles.^{52, 121}

The anterolateral branch of the anterior circumflex humeral artery runs for a short distance next to the tendon of the long head of the biceps within the bicipital groove. This small vessel can be mistaken for a bicipital tendon disorder, particularly on gradient-echo sequences in which arterial flow appears bright.¹²¹

Cross-Sectional Anatomy

The following paragraphs describe the anatomy of the shoulder from the viewpoint of cross-sectional imaging in the four planes often obtained with MRI:

- Axial
- Coronal oblique
- Sagittal oblique
- Abduction, external rotation (ABER)

The descriptions are complemented by Figures 50–1 to 50–4.

Axial Projection (Fig. 50–1)

At the level of the acromioclavicular joint, seen in part A of Figure 50–1, the acromion curves in on the lateral side of the shoulder to meet the distal end of the clavicle. It is not unusual for the ends of the bones to be oriented at slightly different angles.

Part B shows the level of the top of the humeral head. The supraspinatus muscle arches across the humerus from posteromedial to anterolateral and may appear to surround the humeral head. A large, principal tendon arises from the anterior, fusiform portion of the muscle. Small individual tendon slips arise from the posterior supraspinatus muscle, which morphologically resembles a strap muscle. The course of the main tendon is at a slightly different angle from that of the muscle.^{204, 205} The deltoid forms a thick semicircle of muscle external to the supraspinatus. The scapular spine can be noted posteriorly as it runs laterally and superiorly to form the acromion.

In part C, at the level of the top of the coracoid process of the scapula, the humeral head normally has a round shape. The top of the glenoid is usually seen here, but it is not uncommon for the labrum to be inapparent. The supraspinatus muscle projects between the glenoid and the inferior extension of the scapular spine. The infraspinatus tendon emerges anteriorly to attach to the greater tuberosity. Running from posterior to anterior is the superior glenohumeral ligament.

In part D, closer to the base of the coracoid, the superior labrum becomes identifiable. A Hill-Sachs deformity, if present, can be identified at this level or higher.

In part E, the normal posterior labrum has a relatively constant blunt triangular shape. The anterior labrum may vary considerably in shape. It may appear either round or

pointed and may exhibit longitudinal or transverse clefts.^{73, 109, 114, 132} Both anteriorly and posteriorly, the articular cartilage comes to the edge of the glenoid, and this forms an area of increased signal intensity that burrows beneath the internal edge of the labrum and must not be mistaken for a tear.⁹⁹ At this level, the humeral head has an oblong shape with two indentations. Anteriorly, the greater and lesser tuberosities surround the bicipital groove, in which rests the tendon of the long head of the biceps. Posteriorly, a normal, small concavity or flattening of the humerus can be seen.¹⁷⁵ Other structures routinely visualized here include the anterior joint capsule, the middle glenohumeral ligament, and the subscapularis muscle and tendon.

Coronal Oblique Projection (Fig. 50-2)

In part *A* of Figure 50-2, the subscapularis muscle runs anterior to the scapular blade and just beneath the base of the coracoid to attach to the lesser tuberosity. Inferior to this are the flow voids of axillary vessels within the quadrilateral space. Superiorly, the anteriormost extent of the clavicle is the origin of a portion of the deltoid.

In part *B*, more posteriorly, the anterior humeral head may be seen with the greater and lesser tuberosities and the dark bicipital tendon within its groove. The coracohumeral ligament runs at an angle with respect to this plane of imaging, but portions of it may be seen.

Figure 50-2. A-D, MRI coronal oblique views of the shoulder (see text for details). 1, subscapularis muscle; 2, coracoid process; 3, axillary vessels; 4, clavicle; 5, deltoid; 6, lesser tuberosity; 7, greater tuberosity; 8, bicipital tendon; 9, coracohumeral ligament; 10, acromion; 11, humeral articular cartilage; 12, supraspinatus muscle and tendon; 13, superior labrum; 14, inferior labrum; 15, inferior glenohumeral ligament/axillary recess; 16, fat stripe; 17, infraspinatus muscle; 18, infraspinatus tendon.

In part *C*, at the midglenoid, the glenohumeral articulation is well seen. It is best visualized in the coronal projection at the point at which the glenoid is most prominent. Also well seen at this level is the tendon of the supraspinatus and the peribursal fat stripe. A portion of the inferior glenohumeral ligament is seen below the inferior labrum. Although it is not evident here, a thin, crescentic band of preserved red marrow may be seen in the humeral epiphysis, running parallel to the articular cortex.¹⁶⁴

In part *D*, far posterior in the shoulder, the infraspinatus muscle and tendon pass under the acromion to insert on the greater tuberosity. Depending on the degree of internal or external rotation, this attachment site may not always be visualized in the same plane as the muscle. It may be quite difficult in an individual patient to decide where the supraspinatus muscle ends and the infraspinatus begins.

Sagittal Oblique Projection (Fig. 50–3)

In part *A* of Figure 50–3, the four rotator cuff tendons blend at their insertion sites into a fibrous band that appears on magnetic resonance imaging (MRI) as a solid arc of dark signal draped across the humeral head. The deltoid muscle projects external to the rotator cuff. The physal scar is often visible in adults. To distinguish anterior from posterior in the sagittal projection, note that a supine patient's arm usually tilts backward a bit from the shoulder, so as a first approximation the direction the distal humerus points may be taken as posterior.

In part *B*, at the level of the medial humeral head, the rotator cuff muscles are separate from one another. (The infraspinatus and teres minor, however, may be inseparable both anatomically and tomographically.) The biceps tendon is seen close to the humeral head in the rotator interval between the subscapularis and the supraspinatus. The coracoacromial ligament is the dark structure arching anteriorly and inferiorly from the inferior margin of this slightly hooked acromion.

In part *C*, slightly more medial, the lateral aspect of the coracoid process becomes visible. The coracoid is a reliable marker for anterior.

In part *D*, farther medial, the coracoid process arises from its base on the scapula. One of the coracoclavicular ligaments projects between the coracoid and the clavicle.

In part *E*, at the level of the scapular “Y,” the suprascapular artery and nerve are seen running beneath the body of the supraspinatus muscle and through the spinoglenoid notch.

Abduction, External Rotation (ABER) Positioning (Fig. 50–4)

In part *A* of Figure 50–4, a coronal scout image allows sections to be obtained parallel to the humeral shaft and perpendicular to the glenohumeral joint, running in this case from the inferior to the superior glenoid.

In part *B*, at the level of the inferior labrum, the posterior joint space balloons outward as the anterior capsule is placed under tension by this positioning technique.

In part *C*, as in other externally rotated sequences, the

anterior labrum assumes a pointed, triangular shape. The posterior labrum becomes rounded and globular. As the humerus rotates up into position, the medial aspect of the bone now faces anteriorly. The concave shape of the metaphysis is typical of the medial, upper humerus.

In part *D*, at approximately the midglenoid, the anterior band of the inferior glenohumeral ligament is visible.

In part *E*, at the level of the superior glenoid, the course of the tendon of the long head of the biceps brachii is displayed, almost in its entirety in this patient.

Technique

In evaluation of bony trauma, noncontrast computed tomography (CT) of the shoulder is often useful. Contiguous 5-mm sections in the axial plane beginning at the acromioclavicular joint are sufficient to find or exclude fractures. The scan should extend a few centimeters below the most inferior fracture line. If coronal, sagittal, or three-dimensional (3D) reconstruction is desired, thinner cuts will provide smoother reconstructed images. Overlapped 3-mm sections obtained at 2-mm increments, for example, may improve the quality of reconstructed images. A bone algorithm should be employed.³⁰ Helical CT has proved useful in the skeletal system, allowing fast imaging with excellent reconstruction in additional planes at the cost of slight loss of resolution in the plane of primary acquisition.¹⁸¹

CT arthrography is useful for evaluation of the joint capsule and intracapsular structures and for finding loose bodies within the joint. For the double-contrast technique, 0.5 to 3.0 mL of contrast material and approximately 10 mL of room air are introduced into the glenohumeral joint. Contiguous slices are obtained at 3- to 4-mm intervals from a level just above the acromioclavicular joint to below the glenoid fossa.^{30, 34, 159, 180, 183, 184, 213} Single-contrast technique may also be employed.^{66, 91, 166}

CT arthrography has been largely overtaken by MRI as the preferred technique for evaluation of intracapsular structures. MRI allows better concurrent evaluation of extracapsular structures, such as the rotator cuff, and is noninvasive. It does have disadvantages, however. MRI is contraindicated in patients with intraorbital metal, pacemakers, defibrillators, and incompatible intracranial surgical clips. It may ruin such a large number of electronic devices, including implanted drug infusion ports, bone stimulator devices, and hearing aids, that a complete discussion of safety in MRI is beyond the scope of this chapter. Ferromagnetic metallic surgical devices in the region being scanned may ruin the images. (This, of course, may also be a problem with CT.) Claustrophobic patients who find it difficult to tolerate the confinement of a cylindrical superconducting magnet may better tolerate scanning in a low-field-strength open system. Relatively little research has been done to evaluate the diagnostic accuracy of the open scanners.¹¹⁵

MRI depiction of intracapsular structures, the capsule itself, and the undersurface of the rotator cuff is greatly enhanced by a joint effusion, which is sometimes conveniently present concomitantly with disease, particularly in young persons. When an effusion is not present, however,

Figure 50-3. A–E, MRI sagittal oblique views of the shoulder (see text for details). 1, rotator cuff; 2, humeral head; 3, deltoid muscle; 4, subscapularis; 5, bicipital tendon; 6, supraspinatus; 7, infraspinatus; 8, teres minor; 9, acromion; 10, coracoclavicular ligament; 11, conjoint tendon of short head of biceps brachii and coracobrachialis; 12, coracoid process; 13, clavicle; 14, acromioclavicular joint; 15, acromioclavicular ligament; 16, coracoclavicular ligament; 17, scapular spine (root of acromion); 18, suprascapular nerve and artery.

Figure 50-4. A–E, Abduction, external rotation (ABER) oblique axial views of the shoulder. 1, humeral shaft; 2, humeral epiphysis; 3, glenoid; 4, redundant posterior capsule; 5, taut anterior capsule; 6, anterior humeral cortex; 7, anterior labrum; 8, posterior labrum; 9, posterior rotator cuff; 10, inferior glenohumeral ligament; 11 (and arrowheads), biceps tendon, long head.

these structures become more difficult to interpret. To obtain the effect of an effusion, intra-articular gadolinium-diethylenetriamine-penta-acetic acid (Gd-DTPA) can be used. Gd-DTPA, diluted approximately 1:250 with normal saline, is injected into the glenohumeral joint.⁹¹

Palmer and colleagues suggested a solution obtained by mixing 2 mL of gadopentetate dimeglumine (Magnevist, Berlex Laboratories, Wayne, NJ) in 250 mL of normal saline. They mixed 10 mL of this solution with 5 mL of iodinated contrast (60% meglumine diatrizoate), 5 mL of 1% lidocaine, and 0.3 mL of 1:1000 epinephrine.¹⁴⁷

Beltran and coworkers have used 1 to 5 mL of iodinated contrast to confirm intra-articular needle placement fluoroscopically; they then injected a solution obtained by diluting 0.1 mL of gadopentetate dimeglumine in 20 mL of normal saline and mixing with 0.3 mL of 1:1000 epinephrine.⁵

Each of these methods assumes needle placement at fluoroscopy. Palmer's technique allows performance of a single-contrast arthrogram at the time of injection, as may Beltran's, depending on how much iodinated contrast has been used. Some radiologists prefer to achieve intra-articular needle placement sonographically, with MRI guidance, or without imaging guidance, using anatomic landmarks.^{32, 155, 206} In those circumstances, nothing would be gained by injection of iodinated contrast. An alternative procedure is the intra-articular injection of normal saline with acquisition of T2-weighted sequences.²⁰⁹

Diagnostic MRI images of the shoulder depend on a number of technical considerations. The proliferation of varied imaging platforms by numerous manufacturers during the 1990s has made it difficult to generalize about technique and increases the need for all radiologists to become familiar with the capabilities and limitations of their own machines. Recommendations given here are colored by experience with the General Electric (G.E.) Signa 1.5 Tesla systems and must be adapted as appropriate to other magnets. Small field-of-view (FOV) images with thin sections are essential to obtain sufficient spatial resolution. We use a 14- to 16-cm field of view and a 3- to 4-mm section thickness with a 0.5- to 1-mm intersection gap in all projections and for all pulse sequences. The larger field of view, section thickness, and intersection gap are used for larger patients. Local or surface radiofrequency coils, including quadrature coils, provide a sufficient signal-to-noise ratio to support the necessary resolution.

One final technical point that is often overlooked is the importance of stabilizing the shoulder to reduce motion artifact. Motion arises from a combination of respiratory and small voluntary movements by the subject. When the coil allows it, this small amount of motion may be effectively suppressed by placing a sandbag on the shoulder. It is important to be sure of the contents of the sandbag before bringing it into the MRI scanning room. Some "sand" bags actually contain ferromagnetic metallic shot.

There is no uniform agreement concerning the ideal pulse sequences for imaging the shoulder. For evaluation of the rotator cuff, most radiologists use a long repetition time (TR), double-echo sequence obtained in an oblique coronal plane chosen to be parallel to the supraspinatus muscle or perpendicular to the glenoid fossa. Using the

same pulse sequence, we also obtain a second set of images in an oblique sagittal plane perpendicular to the coronal set.

Most published experience with T2-weighted technique is based on the use of spin-echo images, but beginning around 1995, results with fast spin-echo have suggested that it is equally diagnostic.^{3, 17, 169, 182, 187, 219} At least one group of investigators has used T2-weighted gradient-echo images with success.¹⁶⁹ Some radiologists prefer a short TR/TE (echo time) sequence for the sagittal oblique plane, which has the advantage of shorter acquisition time but the disadvantage of lower sensitivity to rotator cuff disease.

For long TR/TE spin-echo sequences, we also recommend that those working on G.E. Signa systems use the "classic" option with frequency centered on the water peak. This provides some fat suppression on the second echo. We do not routinely use other fat-suppression techniques, although they may be useful, particularly when fast spin-echo is preferred to spin-echo imaging.^{3, 148, 158, 162, 182}

For evaluation of glenohumeral instability and the glenoid labrum, we image in the axial plane and use either the long TR, double-echo sequences previously described or a two-dimensional (2D) gradient-echo sequence obtained with a TR of 400 to 600 msec, a TE of 10 msec, and a flip angle of 20 degrees. We prefer to position the patient's shoulder in slight external rotation. Keeping the patient's elbow extended, we rotate the hand so that the palm faces medially and upward, making approximately a 45-degree angle with the tabletop. Placing a wedge cushion under the hand and sandbags across the palm maintains this position without active muscular effort, thus increasing comfort and decreasing motion artifact. Greater external rotation may slightly increase sensitivity to anterior labral tears.²⁰¹

When performing gadolinium MRI shoulder arthrography, we use T1-weighted spin-echo or gradient-echo axial, coronal oblique, and sagittal oblique images with fat saturation. It is important to include at least one set of T2-weighted images, usually in the coronal oblique plane. This allows identification of intrasubstance rotator cuff disease and fluid collections not in communication with the glenohumeral joint.

A fourth imaging plane that may be helpful with MR arthrography is the oblique axial plane, with the patient's shoulder in abduction and external rotation.^{29, 96, 196} If the patient places the hand under the head, palm up, the shoulder will be appropriately positioned. A coronal localizing sequence then allows images to be obtained parallel to the shaft of the humerus.

Rotator Cuff Disease, Impingement, and Instability

Pathophysiology of Rotator Cuff Disease and Impingement

Rotator cuff disease is a common cause of shoulder pain and disability. It is linked with impingement, glenohumeral instability, and bicipital tendon disorders in a complex web of associations. It is impossible to speak or write comprehensively of one without bringing up the others, for whatever one may believe of the causal relationship of these disorders, patients with any one of them have an

increased incidence of the others compared with individuals not so affected.^{80, 129, 136}

In 1991, Fu and coworkers drew on the work of many authors to propose a unifying theory linking rotator cuff disease to impingement and glenohumeral instability.⁵³ *Intrinsic* and *extrinsic* factors, acting together or separately, result in a common endpoint.

Intrinsic factors lead to degenerative changes within the substance of the rotator cuff with increasing age.^{24, 143, 146} The degeneration may result from relative ischemia within the distal portion of the supraspinatus tendon near its insertion site on the greater tuberosity. This zone of relative ischemia, called the *critical zone*, corresponds to the most common site of rotator cuff disease, although its exact location and size vary from one patient to another.^{87, 100, 122, 161} Rotator cuff degeneration may incite secondary proliferative bony changes on the undersurface of the acromion. These changes, in turn, may lead to further cuff degeneration and, ultimately, to a cuff tear.¹⁴⁶

Extrinsic causes of rotator cuff disease relate to mechanical impingement by surrounding structures. The impingement can lead to inflammatory and degenerative change in the underlying tendons. The causes of impingement can be further divided into *primary* and *secondary* types.⁵³

Primary impingement results from contact between the coracoacromial arch or acromioclavicular joint and the underlying tendons.^{9, 53, 129} The coracoacromial arch (consisting of the coracoid process, the coracoacromial ligament, and the undersurface of the anterior third of the acromion), the acromioclavicular joint, and both the rotator cuff tendons and the tendon of the long head of the biceps have a very close anatomic relationship. The supraspinatus tendon passes between the coracoacromial arch superiorly and the humeral head inferiorly to reach its insertion site on the greater tuberosity. The bicipital tendon passes through the same area, coming only slightly more anteriorly. Mechanical compression of these tendons is particularly likely when the shoulder is flexed and internally rotated, as during a tennis serve. Overuse in sports or work accelerates tendon degeneration resulting from either impingement or intrinsic degeneration.^{8, 9, 53, 129, 131, 136}

Neer divides the impingement syndrome into three stages:^{126, 128, 131}

Stage I is characterized by edema and hemorrhage within the distal supraspinatus tendon and is usually reversible with conservative treatment.

In *stage II* impingement syndrome, there are tendinitis and thickening and fibrosis of the subacromial-subdeltoid bursa. The bursal changes compound the problem by decreasing the subacromial space available to the tendons. In *stage III* disease, a partial or a full-thickness tear of the rotator cuff or biceps tendon occurs, along with osseous changes including anterior acromial osteophyte formation and degenerative changes in the greater tuberosity.

Stage III lesions usually occur in patients older than 40 years of age, whereas stage I and II lesions are found in younger adults. Long-standing rotator cuff tears may lead, furthermore, to erosions of the humerus and to glenohumeral destruction, termed *rotator cuff arthropathy*.^{126, 128, 131}

Whereas primary impingement syndrome is caused by the effects of the coracoacromial arch and acromioclavicu-

lar joint on the rotator cuff in a normally positioned and functioning glenohumeral joint, *secondary impingement syndrome* is related to glenohumeral instability. Secondary impingement usually occurs in young athletic individuals involved in sports that demand overhead arm movement. Repetitive external rotation in abduction, as during the cocking phase of a baseball pitch, may lead to laxity of the capsule and mild instability. This is initially compensated for by an increase in the tone of the rotator cuff, which pulls the humeral head into the glenoid and enhances stability. With continued vigorous activity, however, the rotator cuff loses its ability to compensate, and the humeral head subluxates. The subluxation results in secondary impingement.^{53, 79, 94} This atraumatic form of instability is often multidirectional and may damage different portions of the labrum or rotator cuff, depending on individual circumstances.¹⁶⁶

Patients with impingement syndrome present with a "painful arc" consisting of pain over the anterolateral humeral head exacerbated by flexion and abduction, particularly in the 70-degree to 120-degree portion of the arc. Orthopedic surgeons test for impingement by injecting lidocaine into the subacromial region. If the condition is present, this temporarily relieves the pain.

Differentiating primary from secondary impingement may be clinically difficult. Patients with secondary impingement are usually younger than those with primary impingement, and they may relate the pain to a very specific activity. A baseball pitcher with pain restricted to the late cocking or early acceleration phase of throwing is a typical example.

At physical examination, a relocation maneuver may reveal the subtle instability found in these patients. With the patient supine and the shoulder abducted and externally rotated, posteriorly directed force is applied to the anterior, proximal humerus. As the humerus is reduced posteriorly, the patient's pain is alleviated.^{78, 94}

It is important to differentiate primary from secondary impingement because the treatments differ significantly. Patients with primary impingement are usually treated with an anterior acromioplasty, with appropriate attention to the rotator cuff and biceps tendon. In patients with secondary impingement, treatment is aimed at the instability.^{79, 80, 106, 107, 129, 131}

Coracoid Impingement

A distinct subtype of impingement, occurring with the shoulder flexed, internally rotated, and adducted, is associated with impingement of the coracoid process upon the lesser tuberosity. This rare cause of anterior shoulder pain may be associated with an unusually long and medially oriented coracoid process. It may also follow a Bristow procedure, in which the tip of the coracoid process is moved further medially along the glenoid neck to correct anterior instability, or an osteotomy of the glenoid neck to correct posterior instability. Patients without an iatrogenic risk factor often engage repeatedly in occupational or recreational activities requiring overhead motion in internal rotation.^{8, 36, 56}

Imaging of Rotator Cuff Disease

After retrospective studies of Kneeland and colleagues in 1986⁹⁰ and 1987⁸⁹ indicated that MRI had potential for

MRI, magnetic resonance imaging.

identifying rotator cuff pathologic conditions, MRI quickly became established as an accurate, noninvasive means of diagnosing rotator cuff tears.^{43, 221} Reported sensitivities for full-thickness rotator cuff tears have ranged from 80% to 100%, and specificities from 94% to 100%. Arriving at a diagnosis of partial-thickness tears is more problematic. Sensitivities of 10% to 92% have been reported, with specificities of 83% to 100% (Table 50-1).

MRI Appearance

MRI can depict the continuum between rotator cuff degeneration or tendinopathy and partial or full-thickness rotator cuff tears. Intrinsic cuff degeneration or tendinopathy is seen as increased signal intensity within the distal tendon on proton-density images; this persists but does not intensify on T2-weighted images.

Partial tears of the tendon may be intratendinous in

location or may occur on either the bursal or the articular side of the tendon. They are most common along the articular surface of the cuff.¹⁹⁹ On MRI, partial tears are depicted as focal areas of increased signal intensity on short TE images; these areas increase in relative signal intensity on long TE images but need not match the signal intensity of joint fluid (Figs. 50-5 and 50-6). The abnormal focus does not extend through the entire thickness of the tendon. There may be increased fluid within the glenohumeral joint, particularly if the partial tear is on the articular side. Alternatively, fluid may be seen within the subacromial-subdeltoid bursa if the partial tear lies on the bursal side of the tendon.

In a full-thickness rotator cuff tear, the tendon is interrupted by an abnormal focus of bright signal intensity extending across its complete superior to inferior extent on at least one image. The signal intensity within the tendon gap is usually notably bright on T2-weighted images, pre-

Figure 50-5. Articular side partial tear. *A*, T2-weighted (TR = 2500 msec, TE = 70 msec) coronal oblique image. *B*, T2-weighted (TR = 2500 msec, TE = 70 msec) sagittal oblique image. On the articular side of the supraspinatus tendon is a bright gap (*arrow*) covered on the bursal side with a thin layer of remaining tendon. Increased joint fluid is present, and some fluid is present in the subdeltoid bursa.

Figure 50-6. Possible tendinopathy, tendinitis, or partial tear.

A, Proton-density-weighted (TR = 2500 msec, TE = 14 msec) coronal oblique image. The central tendon of the supraspinatus muscle is interrupted by an ill-defined area of increased signal in the critical zone near its attachment site (*arrow*). Note the suprascapular neurovascular structures in the suprascapular notch (*small arrow*).

B, T2-weighted (TR = 2500 msec, TE = 70 msec) coronal oblique image. The small area of increased signal in the supraspinatus tendon (*arrow*) has become relatively brighter with T2 weighting, and it is quite focal. This probably represents a partial tear of the supraspinatus tendon. Fluid can be seen in the subdeltoid bursa (*small arrow*).

C, T2-weighted (TR = 2500 msec, TE = 70 msec) sagittal oblique image. This section is farther medial than the partial tear, yet a tiny bright spot is present near the anterior edge of the supraspinatus muscle (*arrow*). This is probably joint fluid in the biceps interval that can be mistaken for a rotator cuff tear. Fluid in the subacromial-subdeltoid bursa is also visible.

Figure 50-7. Full-thickness tear.

A, Proton-density-weighted (TR = 2500 msec, TE = 14 msec) coronal oblique image. A gap is present in the supraspinatus tendon near its insertion site (*arrow*). Some proliferative changes affect the acromioclavicular joint, including a small, downward-pointing spur (*small arrow*).

B, T2-weighted (TR = 2500 msec, TE = 70 msec) coronal oblique image. The tendon gap is very bright (*arrow*) and is most likely filled with fluid. No intact tendon exists above or below the abnormal area.

C, Proton-density-weighted (TR = 2500 msec, TE = 14 msec) sagittal oblique image. Anterosuperiorly, the normal dark band of the rotator cuff is interrupted by a fuzzy area of relatively increased signal (*arrowheads*).

D, T2-weighted (TR = 2500 msec, TE = 70 msec) sagittal oblique image. The anterior part of this area becomes very bright (*arrow*). The remainder brightens only slightly. Often a tear is adjacent to or surrounded by an area of tendinopathy.

sumably as a result of fluid (Figs. 50-7 to 50-9). Fluid within the subacromial-subdeltoid bursa is a common finding in full-thickness tears, although it may occasionally be present without a tear when the patient has bursitis.^{45, 72} Some full-thickness tears lack fluid-intensity signal because of a paucity of fluid within the joint or because the tendon gap is filled with scar.¹⁶⁰ Other useful signs include tendon retraction and atrophy of the involved muscles with associated fatty infiltration. Tendon retraction becomes more obvious as the size of the tear increases, and it may be inapparent in small tears.¹⁶⁰ Fatty infiltration of the muscle is expected only in relatively chronic tears (Fig. 50-10).

Large tears may be surprisingly subtle if there is little fluid in the joint to communicate with the tendon gap or subacromial bursa. Occasionally, tendon retraction may bring the amputated stump to rest along the medial surface of the humeral head so that the humeral cortex resembles a smooth continuation of the tendon. In these cases, cephalad migration of the humeral head may be the most obvious sign of tearing (Fig. 50-11).

Another occasional accompanying sign is irregularity of the bony elements of the glenohumeral joint as a result of rotator cuff arthropathy (Fig. 50-12). An irregular greater tuberosity has been shown to correlate with rotator cuff

Figure 50-8. Fat-suppression technique. *A*, Proton-density-weighted (TR = 2000 msec, TE = 15 msec) coronal oblique image. *B*, T2-weighted (TR = 2000 msec, TE = 90 msec) coronal oblique image. Fat-suppression techniques may increase the conspicuity of a rotator cuff tear (*asterisks*) as well as that of a small cystlike defect in the humeral head, but less detail may be discernible elsewhere. (Courtesy of Thomas Hedrick, M.D., Houston.)

tears at sonography.²¹⁴ To our knowledge, this has not been tested with MRI. Cystlike lesions of the humeral head have a modest correlation with the presence of rotator cuff disease but are also common in asymptomatic individuals.^{74, 125}

Rotator Interval Tears

Rotator cuff tears most commonly begin in the supraspinatus tendon, usually near its anterior edge. As the tear enlarges, it may extend completely across the anterior to

posterior dimension of the supraspinatus muscle and tendon, to involve parts or all of the infraspinatus and subscapularis. When the tear occurs at the critical zone of the supraspinatus muscle and spreads anteriorly into the subscapularis, it crosses and involves the intervening rotator interval. Isolated tears of the rotator interval also occur, although uncommonly. They are usually the result of an anterior dislocation. Synovium may herniate from the glenohumeral joint into the rotator interval. With MRI, it can be difficult, if not impossible, to distinguish an isolated rotator interval tear from herniated synovium, especially

Figure 50-9. Large cuff tear. *A*, T2-weighted (TR = 2500 msec, TE = 70 msec) coronal oblique image. Bright-signal fluid spills from the glenohumeral joint through a large rent in the rotator cuff into the subacromial-subscapular bursa. Joint fluid also tracks down the sheath of the long head of the biceps brachii muscle (*arrow*). The supraspinatus tendon is retracted (*small arrow*). *B*, T2-weighted (TR = 2500 msec, TE = 70 msec) sagittal oblique image. The large size of this tear may be best appreciated on this sagittal image. At surgery, the tear included all of the supraspinatus, most of the infraspinatus, and the superior part of the subscapularis.

Figure 50-10. Atrophy. *A*, T2-weighted (TR = 2500 msec, TE = 70 msec) coronal oblique image. The supraspinatus muscle and tendon are retracted to the glenoid (*arrow*), and the humeral head contacts the acromion. *B*, Proton-density-weighted (TR = 2500 msec, TE = 14 msec) sagittal oblique image. The supraspinatus (S) and infraspinatus (I) muscles are markedly atrophied and infiltrated with fat.

without administration of intra-articular contrast medium.^{140, 177}

Isolated Subscapularis Tears

Isolated tears of the subscapularis tendon are rare. Deutsch and coworkers studied these tears in 13 patients and found that all were caused by a definable traumatic incident, usually forced hyperextension or external rotation of an abducted shoulder.³⁵ At MRI, subscapularis tendon injuries are evident in all three usual imaging planes—axial, coronal oblique, and sagittal oblique—although they may be most obvious on axial images. An area of disorganized tendon morphology is identified with increased signal intensity on T2-weighted images.^{152, 219}

Pitfalls in Diagnosis

To avoid overcalling rotator cuff pathologic findings, one must be aware of a normal area of increased signal intensity in the distal supraspinatus tendon. It is located approximately 1 cm proximal to the insertion site of the tendon. It has been described by some authors as isointense with muscle.^{82, 117} Others refer to it merely as increased in signal intensity without providing a point of reference. Although most authors have noted it on short TE technique, Kaplan and colleagues⁸² found it to be most apparent on gradient-echo images, and Mirowitz¹¹⁷ also noted it in some T2-weighted images. It has been identified in asymptomatic individuals and does not necessarily represent a pathologic finding. Attention to tendon morphology may help distin-

Figure 50-11. Large chronic cuff tear. *A*, T2-weighted (TR = 2500 msec, TE = 70 msec) coronal oblique image. Relatively little joint fluid is present. The supraspinatus tendon is retracted nearly to the glenoid (*black arrow*), and the humeral head has translated superiorly and contacts the acromion (*small black arrow*). Migration of the humeral head, leaving a partially empty glenoid fossa (*white arrow*), is one of the most obvious signs of rotator cuff tearing in this patient. *B*, T2-weighted (TR = 2500 msec, TE = 70 msec) sagittal oblique image. The acromion has a hooked shape. Note again the close apposition of the acromion and the humeral head.

Figure 50-12. Cuff arthropathy. *A*, Proton-density-weighted (TR = 2500 msec, TE = 14 msec) sagittal oblique image. Atrophy of the supraspinatus (S) and infraspinatus (I) muscles attests to long-standing rotator cuff tear. *B*, Proton-density-weighted (TR = 2500 msec, TE = 14 msec) sagittal oblique image. Jagged, irregular humeral cortex (arrowheads) is typical of cuff arthropathy. On this film, the anterior part of the shoulder is to the right.

guish normal from pathologic increases in signal intensity. A normal tendon should taper smoothly from the musculotendinous junction to the insertion site.

Several theories have been proposed to explain this area of increased signal intensity. It may represent subclinical degenerative change within the tendon.^{117, 160, 222} Erickson and coworkers noted increased signal intensity on T1-weighted images that they attributed to the “magic angle phenomenon,” in which an artifactual focus of increased signal intensity may occur on short TE images of a tendon oriented 55 degrees to the constant magnetic field.⁴² They postulated that such increased signal intensity may also be expected on intermediate-weighted images but not on long TE images. Timins and colleagues, including Erickson, bolstered this suggestion in 1995 by showing that the area of increased signal intensity changed position within the tendon with changes in patient position.¹⁹³

Another possible explanation concerns positioning of the shoulder. If the arm is internally rotated, the distal supraspinatus and infraspinatus tendons move anteriorly. This carries the distal infraspinatus tendon and small posterior supraspinatus tendon slips forward into the plane of the main supraspinatus tendon on oblique coronal images. The infraspinatus muscle routinely has multiple tendon slips with muscle interposed between them.

The supraspinatus tendon may be divided into two structures—the anterior main tendon and smaller posterior slips. In addition, there are bits of fatty connective tissue between the supraspinatus and infraspinatus muscles. This fatty tissue, along with the muscle interdigitated between slips of infraspinatus tendon or between the principal anterior supraspinatus tendon and the smaller posterior tendon slips, may result in an apparent area of increased signal intensity on short TE images that fades on T2-weighted images. One may reach the correct conclusion by following the intact tendons on oblique sagittal images.^{31, 99, 133, 204}

Rotator cuff tears may be diagnosed by CT or MR arthrography using essentially the same diagnostic criteria

employed with conventional arthrography and conventional MRI. One simply searches for extravasation of contrast from the glenohumeral joint into the substance of a tendon or through the cuff into the subacromial-subdeltoid bursa. One also looks for evidence of intrasubstance high signal intensity on T2-weighted images. Nonarthrographic MRI of the shoulder already has a high degree of accuracy, particularly for full-thickness tears, so any substantial gain in accuracy with MR arthrography is likely to be in the diagnosis of partial tears (Fig. 50-13).

Postsurgical Imaging

MRI may be helpful in assessment of the rotator cuff after surgery. Results, however, must be cautiously coordi-

Figure 50-13. Partial tear of the supraspinatus muscle. T1-weighted (TR = 500 msec, TE = 14 msec), sagittal oblique image with fat saturation obtained after intra-articular injection of dilute gadolinium. Gadolinium fills a partial tear of the under-surface of the belly of the supraspinatus muscle (arrow). No bright signal is present in the subacromial-subdeltoid bursa, thus effectively excluding a full-thickness cuff tear.

Figure 50-14. Flat acromion. Proton-density-weighted (TR = 2500 msec, TE = 14 msec) sagittal oblique image. The undersurface of the acromion has a perfectly straight, flat shape. The arrow indicates the coracoacromial ligament.

nated with clinical status. In a majority of patients, repaired rotator cuff tears exhibit increased signal intensity on T2-weighted images.^{145, 188} Recurrent cuff tears may enable the diagnosis with a high degree of accuracy on the basis of the presence of distinct, fluid-intensity signal within the tendons on T2-weighted images, but the significance of the finding is not always clear.^{103, 145} Spielmann and colleagues, studying the supraspinatus and infraspinatus tendons of a group of 15 asymptomatic patients after rotator cuff repair, found MRI evidence of rotator cuff tear in 11 (37%) of the 30 tendons. They also found subacromial-subdeltoid effusions, joint effusions, and bone marrow edema to be common in their patients.¹⁸⁸

Imaging of Primary Impingement

MRI can be quite useful in the assessment of patients with primary impingement. These patients frequently have narrowing of the space between the acromion and the superior surface of the humeral head that is well delineated on MR images in either the sagittal oblique or the coronal oblique projection.^{85, 176} This narrowing may be related to the configuration of the anterior acromion or the acromioclavicular joint.

Bigliani and coworkers described an association between the shape of the undersurface of the anterior acromion and the likelihood of rotator cuff tear.⁹ They established three categories of acromial shape; *type I* is flat (Fig. 50-14), *type II* is curved, and *type III* is hooked anteriorly. Despite some debate about the nature of the hook, it seems likely that most arise as enthesophytes at the origin of the coracoacromial ligament.^{38, 57}

Bigliani and coworkers found an increasing incidence of rotator cuff tears with type II and particularly with type III acromia.⁹ The association of hooked acromia and rotator cuff tears has been confirmed by others.^{40, 143} However, the practical application of the work of Bigliani and colleagues to interpretation of shoulder MRI is somewhat problematic. They performed their investigation using conventional radiography, and with this modality, the eye perceives a summation shadow composed of the entire acromion. MRI, of course, demonstrates acromial shape tomographically. On MR images, it is not unusual for the shape of the acromion to change from section to section. Thus, for example, an acromion with a flat configuration in one oblique sagittal section may have a curved shape in another (Fig. 50-15). Slight variations in positioning for the conventional radiographic outlet view may also change the apparent shape of the acromion. These factors contribute to considerable interobserver variability in classification of acromial shape.^{68, 153}

In practice, the authors habitually include an assessment

Figure 50-15. Acromial variation. A, Proton-density-weighted (TR = 2500 msec, TE = 14 msec) sagittal oblique image. This relatively laterally placed section demonstrates an acromion with a smoothly curved undersurface. B, Proton-density-weighted (TR = 2500 msec, TE = 14 msec) sagittal oblique image. More medially, the same acromion has a hooked shape (arrow at hook). Arrowheads indicate the coracoacromial ligament.

of acromial morphology in interpretation of shoulder MRI (or supraspinatus outlet views) but add modifying adverbs such as "gently curved" or "sharply hooked" to help the reader form a mental image of the acromial shape. As an alternative, measurement of the acromial angle gives a numeric assessment of acromial shape with acceptably low interobserver variability, although this has been tested only on outlet views of the shoulder and not on MR or CT images.²⁰⁰ The acromial angle should probably not be used in interpretations without a prior common understanding with referring physicians.

A low-lying acromion has also been implicated as a cause of impingement. The acromion is considered to be low if its inferior border is lower than that of the clavicle at the acromioclavicular joint. Unfortunately, there are no criteria for distinguishing a low-lying acromion from a high-riding clavicle (such as may result from a previous acromioclavicular joint separation).⁸³

An os acromiale occurs as a normal variant in approximately 8% of people. Since the 1930s, it has been considered to result from a failure of fusion of one of three ossification centers of the acromion. A study of 270 scapulae in 1993 found no support for this venerable theory and instead suggested a single site of occurrence, with the free fragment approximating one-third the length of the acromion.³⁹ There appears to be an association between the presence of an os acromiale and development of impingement syndrome and rotator cuff tear.^{39, 124, 151} An os acromiale may be identified on axial and sagittal oblique images as a linear interruption of the marrow of the acromion (Fig. 50-16).¹⁵¹

Degenerative changes at or near the acromioclavicular joint are variously considered either a cause or a result of impingement and rotator cuff disease. These include hypertrophic changes involving soft tissue within the joint capsule as well as osteophytes that may project inferiorly from the acromion or clavicle and enthesophytes at the origin of the coracoacromial ligament. Spurs may visibly distort the supraspinatus muscle as it passes below them. At times, it may be difficult to distinguish a spur from a tendinous or ligamentous attachment site, particularly because spurs may develop at such sites (Figs. 50-17 and 50-18). Some authors believe that spurs always contain marrow and thus match other marrow-containing bones in signal intensity.⁸² Our experience and that of others suggest that this is generally, but not invariably, true.⁵⁸

Thickening of the acromial origin of the coracoacromial ligament is associated with impingement syndrome even without enthesophyte formation.⁵⁴ It may be identified on sagittal oblique MR images.

Although an association exists between these configurations of the coracoacromial arch and impingement syndrome, any of these findings may also be seen in asymptomatic individuals. A patient may, in fact, have visible indentation of the tendon by a portion of the coracoacromial arch and have no symptoms, much as an asymptomatic person may have a herniated lumbar disk. At the same time, a patient may have no visible indentation of the cuff yet clinically have impingement syndrome. This is partly because impingement is generally positional. Open MRI units may allow greater freedom of positioning, so that the patient can be imaged in the position in which

Figure 50-16. Os acromiale. A, T2-weighted gradient-echo (TR = 700 msec, TE = 10 msec, flip angle = 20 degrees) axial image. A high-signal-intensity line (arrows) runs through the acromion and demarcates the division between the anterior os acromiale and the remainder of the acromion. B, T2-weighted (TR = 2500 msec, TE = 70 msec) sagittal oblique image also demonstrates a dividing line crossing the acromion (arrow). A large, full-thickness rotator cuff tear is visible as well (asterisk).

Figure 50-17. Spur. Fast spin-echo, T2-weighted sagittal oblique image. A spur containing marrow projects from the undersurface of the otherwise flat acromion at the attachment site of the coracoacromial ligament (arrow). The conjoint tendons of the short head of the biceps brachii muscle and the coracobrachialis are seen originating from the coracoid process.

difficulties occur, thus increasing the chance of catching the guilty anatomic feature in action.^{13, 51, 59-61} Because of imperfect correlation between impingement and the anatomic features associated with it, impingement syndrome remains a clinical diagnosis. These findings may, however, reasonably be taken as support of clinically suspected im-

Figure 50-18. Spurious spur. Proton-density-weighted (TR = 2500 msec, TE = 14 msec) coronal oblique image. A slender, black structure projects from the undersurface of the lateral acromion (small arrow). It represents a slip of deltoid tendon or a portion of the coracoacromial ligament (or both, as their fibers may fuse), but it may be mistaken for a spur. A small area of decreased signal (arrow) in the greater tuberosity or, in other cases, a small cyst is a common finding and may be associated with rotator cuff disease.

pingement or may form a basis for suggestion of the diagnosis.

Pathophysiology of Glenohumeral Instability

Glenohumeral joint stability depends on the supporting and restraining effect of the glenoid labrum, the joint capsule including the glenohumeral ligaments, and the rotator cuff. With failure of these structures, the glenohumeral joint becomes unstable. Instability may present clinically and anatomically as either subluxation or frank dislocation and may manifest chronically, recurrently, or as an isolated episode. Shoulder dislocations, which most commonly occur in an anterior and subcoracoid location, are usually the result of acute trauma. During an initial episode of dislocation, the glenoid labrum and anterior capsule may become damaged, and an impaction fracture of the posterolateral humeral head, or Hill-Sachs deformity, may occur. These lesions predispose to recurrent dislocation, often after minimal or no trauma. Recurrent dislocations are common in young patients but become progressively less common with advancing age; they are relatively rare after age 40 years.^{4, 33, 107, 150, 198} Some patients can, and do, dislocate the shoulder voluntarily.¹⁶⁸

Atraumatic instability has been considered less common than traumatic instability.¹⁰⁷ Concern is growing in the orthopedic community, however, about atraumatic instability as a cause of both labral abnormalities and rotator cuff disease due to secondary impingement. A typical patient is a young athlete involved in sports requiring repetitive overhead motion; the stereotypical example is a baseball pitcher. During overhead motion (the late cocking and early acceleration phases of a baseball pitch), the humeral head may come in contact with the posterior-superior glenoid labrum, pressing it, in turn, into the adjacent posterior rotator cuff.

Theoretically, this contact becomes pathologic in some people because of overuse, particularly in the context of inadequate conditioning of the supporting muscles and resulting microinstability. Contact leads to tearing of the posterior-superior glenoid labrum and the adjacent rotator cuff. Anterior instability may occur during the deceleration phase of throwing and may be accompanied by anterior labral tears.^{78, 94, 166} Labral tears beginning posteriorly and superiorly may propagate farther along the labrum, producing SLAP lesions.

In 1990, Snyder and colleagues¹⁸⁶ divided SLAP lesions into four types, depending on the nature of the labral injury and whether there is associated biceps tendon damage:

In *type I* lesions, the labrum is frayed, but it and the biceps tendon are not torn from the glenoid.

In *type II* lesions, the labrum is stripped from the glenoid with the biceps tendon.

In *type III* lesions, there is a bucket-handle tear of the labrum.

In *type IV* lesions, the bucket-handle tear extends into the biceps tendon.

In 1995, Maffet and coworkers expanded the classifica-

tion of Snyder and colleagues to account for additional injury patterns¹⁰²:

In *type V* lesions the tear involves the labrum from the anterior-inferior position to the posterior-superior position.

In *type VI* lesions one finds an unstable flap tear of the labrum and separation of the biceps tendon from its anchor.

In *type VII* lesions, the labral tear extends anteriorly beneath the middle glenohumeral ligament.

Not all SLAP injuries are the result of instability. They may also be caused by sudden, violent traction on the arm, as occurs when catching a heavy object, or by falling on an outstretched arm.^{62, 66, 78, 94, 102}

Imaging of Glenohumeral Instability

Labral Tears

MRI, CT arthrography, and MR arthrography can often demonstrate the anatomic residua of prior episodes of instability. Identification of the stigmata of instability, however, does not indicate whether the problem is ongoing, because (1) anatomic changes may occur at a single episode of dislocation and (2) it is rare to identify actual displacement of the humeral head at the time of imaging. The imaging signs of instability include labral and glenoid rim abnormalities, capsular stripping, and deformities of the humeral head. Although practically any combination of injuries may occur in an individual patient, certain groupings of anatomic abnormalities occur repeatedly (Table 50–2).

Tears of the glenoid labrum are identified by either complete absence of a portion of the labrum, displacement of the labrum from the glenoid rim, or abnormal linear areas of increased signal intensity within the labrum at MRI (Table 50–3).^{55, 63, 84, 97, 174, 220} Similar diagnostic criteria

are used at CT or MR arthrography (Figs. 50–19 and 50–20). In addition, contrast entering the labrum or tracking beneath the labrum to the external surface of the joint is consistent with a tear. When the tear has formed a displaced bucket handle, the fragment creates at double-contrast CT arthrography a characteristic rounded area of attenuation that is less than that of normal labral tissue but greater than that of gas, termed the “cheerio sign.”⁷⁵ The bucket-handle fragment may also be identified at MRI or MR arthrography as a low-signal-intensity intra-articular body.¹²⁰

Good results in diagnosis of labral tears have been reported for MRI, CT arthrography, and MR arthrography, albeit somewhat less consistently for the first two than for MR arthrography (see Table 50–3). Relatively few studies have directly compared their performances. In 1993, Chandnani and coworkers compared MRI, MR arthrography, and CT arthrography and found MR arthrography to be the most sensitive in detecting labral tears (96%); it also offered the best evaluation of the inferior labrum and inferior glenohumeral ligament.²² In 1999, Roger and colleagues compared conventional arthrography, CT arthrography, and MR arthrography in 17 throwing athletes and discovered that MR arthrography was both more sensitive and more specific than the other modalities, not only for labral abnormalities but also for rotator cuff lesions.¹⁶⁶

Pitfalls and Variants in Diagnosis of Labral Tears

The appearance of the labrum has many normal variations. The CT arthrographic configuration of the posterior labrum is rounded, and the MRI appearance has been described as usually triangular. The configuration of the anterior labrum may vary considerably from one individual to another, and in the same person labral shape changes with rotation of the humerus.^{123, 174} With internal rotation,

Table 50–2. “Alphabet Soup” of Glenohumeral Instability and Glenoid Lesions

Acronym	Stands for	Description	Brief Citation	Reference No.
SLAP	Superior labrum, anterior to posterior	Labral tear stretching across superior portion of labrum, crossing origin of long head of biceps brachii muscle	Andrews, 1985 Legan, 1991 Cartland, 1992 Grauer, 1992 Hodler, 1992 Hunter, 1992 Monu, 1994 Maffet, 1995 Handelberg, 1998	2 97 18 62 71 75 120 102 66
HAGL	Humeral avulsion of the glenohumeral ligament	Detachment of capsule and inferior glenohumeral ligament from their anterior humeral attachment site; uncommon lesion first described in 1942	Nicola, 1992 Wolf, 1995 Tirman, 1996 Bokor, 1999	139 215 195 12
GLAD	Glenolabral articular disruption	Tear of anterior-inferior glenoid labrum with associated injury to glenoid articular cartilage; lesion is caused not by instability but by an impaction injury	Neviaser, 1993 Sanders, 1999	135 171
ALPSA	Anterior labroligamentous periosteal sleeve avulsion lesion	Periosteum of the anterior-inferior glenoid remains intact, whereas labrum is displaced medially and rotated inferiorly	Neviaser, 1993	134

Table 50–3. Performance of CT Arthrography, MRI, and MR Arthrography in Diagnosis of Labral Tears

Brief Citation	Reference No.	No. of Patients	Labral Tears: Sensitivity/Specificity/Accuracy (%)*	Comment
CT Arthrography

Palmer, 1995	149	121	92/92/92	—
Cvitanic, 1997	29	92	96/97/–	Tested ABER position and found better performance with combined ABER and axial images than with either alone (44% sensitivity, 92% specificity for axial images alone)
Willemsen, 1998	212	44	93/80/89 (Bankart lesions) 89/89/89 (SLAP lesions)	Used intra-articular saline solution
Bencardino, 2000	7	52	89/91/90 (SLAP lesions)	Found 76% of SLAP lesions correctly graded by MR arthrography

*As given in the original article; not recalculated or derived from data within the article.

ABER, abduction, external rotation; CT, computed tomography; MRI, magnetic resonance imaging; SLAP, superior labrum, anterior and posterior.

Figure 50–19. Labral damage, as shown on a double-contrast CT arthrogram. Gas within the joint capsule projects immediately adjacent to the glenoid cortex (arrow). The anterior labrum is missing.

the anterior labrum assumes a large, globular configuration; with external rotation, it is attenuated and pointed (Fig. 50–21; see Fig. 50–4). The anterior aspect of the labrum may exhibit horizontal clefts or vertical notches. If this pattern is seen posteriorly, however, it suggests a tear. With gradient-echo imaging, an area of smooth, linear high signal intensity within the anterior labrum may occasionally be seen. This finding alone does not indicate a tear; however, its cause has not been ascertained.^{73, 109, 114, 132}

Some normal structures may be misinterpreted as labral tears. The hyaline articular cartilage of the glenoid extends under the base of the labrum.^{99, 175} At MRI, this produces a line of bright signal intensity that may resemble a tear. At the level of the subscapularis tendon, the middle glenohumeral ligament runs parallel to the anterior labrum and also shows low signal intensity. The space between the ligament and the labrum may mimic a tear along the outer border of the labrum, but its true nature is usually revealed when one follows the ligament along its normal course on sequential images (Fig. 50–22).

Superiorly, the sublabral recess or foramen can mimic a labral tear, particularly when intra-articular contrast material enters the recess.⁹⁵ A collection paralleling the shape

Figure 50-20. Anterior labral avulsion and periosteal stripping. T1-weighted (TR = 500 msec, TE = 14 msec), fat-saturated, axial oblique MR arthrogram image in abduction and external rotation. The anterior labrum has been avulsed from the glenoid rim with a short segment of periosteum, allowing the intra-articular gadolinium solution (arrow) to flow between these structures and the glenoid.

Figure 50-22. Labral pitfalls in diagnosis. Proton-density-weighted (TR = 2000 msec, TE = 14 msec) axial image. The anterior labrum and capsule proved to be normal at surgery. The labrum (small arrow) is separated from the glenoid rim by an unusually thick and easily seen layer of articular cartilage. The middle glenohumeral ligament (arrow) runs parallel to the labrum, separated from it by a bright line of connective tissue that might be interpreted as a tear.

Figure 50-21. Effect of rotation. A, Proton-density-weighted (TR = 2500 msec, TE = 14 msec) axial image. With the humeral head in internal rotation (arrow indicates the position of the bicipital groove), the anterior labrum has a rounded configuration (small arrow). B, Gradient-echo axial image. With external rotation, the same anterior labrum assumes a pointed, triangular configuration (arrow). The attachment of the joint capsule to the tip of the labrum can be appreciated.

Figure 50-23. Sublabral recess. T1-weighted (TR = 500 msec, TE = 14 msec), fat-saturated, coronal oblique MR arthrogram image. A smooth-bordered collection of gadolinium (*arrow*) parallels the cortex of the superior glenoid. A small amount of signal also enters the articular surface of the superior labrum in a fashion typical of a type I SLAP (superior labrum, anterior and posterior) lesion (*small arrow*).

of the bony glenoid is probably a normal structure, whereas a collection that turns in a lateral direction into the substance of the labrum is most likely a tear (Figs. 50-23 and 50-24).^{7, 202} The exact location of the fluid collection may

Figure 50-24. SLAP (superior labrum, anterior and posterior) lesion. T1-weighted (TR = 500 msec, TE = 14 msec), fat-saturated coronal oblique MR arthrogram image. Gadolinium (*arrow*) enters the substance of the labrum and turns laterally, away from the glenoid. In this case, the high signal continues to the anterior edge of the labrum, suggesting a bucket-handle tear or type III SLAP lesion.

also provide a hint, as a normal recess or foramen should not extend posterior to the biceps origin, whereas a labral tear often (but not invariably) does.^{185, 202} An absence of the anterior-superior glenoid labrum may be paired with a thick, cordlike middle glenohumeral ligament, a combination called the *Buford complex*.¹⁹⁷

Interpretation of labral images may be particularly difficult in elderly patients because of the considerable overlap between pathologic labral changes and changes associated with normal aging. Intrasubstance degenerative changes are noted in individuals after age 30 years and become increasingly evident with advancing age.^{33, 157} On proton-density or gradient-echo images, these may produce globular increased signal intensity within the labrum.^{109, 132} The labrum may also appear small in older adults.

Other Structures

The anterior joint capsule and glenohumeral ligaments are also important in maintaining shoulder stability.¹⁹⁸ In abduction and external rotation, the glenohumeral ligaments restrain the humeral head and prevent anterior instability. Because of the capsular tension produced by fluid in the joint, capsular abnormalities may be most easily diagnosed with arthrographic technique and either CT or MRI (Figs. 50-25 and 50-26). The anterior capsule may arise from various positions on the neck or edge of the glenoid or from the labrum.^{34, 123} The origin is easily demonstrated by these techniques, but a suspected association between a more medial capsular origin and glenohumeral instability has not been substantiated.^{26, 149}

Figure 50-25. Posterior capsular tear. T1-weighted (TR = 500 msec, TE = 14 msec), fat-saturated, axial MR arthrogram image. A tear in the posterior joint capsule (*asterisk*) allows gadolinium to escape into the adjacent soft tissues. The anterior labrum has been avulsed as well (*arrow*).

Figure 50-26. Humeral avulsion of the glenohumeral ligaments (HAGL lesion). T1-weighted (TR = 500 msec, TE = 14 msec), fat-saturated axial MR arthrogram image. A tear in the anterior capsuloligamentous complex is clearly visible (arrow) near its insertion on the humerus. Whether the tear is close enough to the humerus to constitute a true HAGL lesion is debatable.

Glenohumeral dislocation can result in bony abnormalities that are sometimes visible on plain films but are clearly identified on either CT scans or MR images. As the humeral head dislocates anteriorly, it impacts on the anterior glenoid rim, producing a bony Bankart lesion (anterior glenoid rim fracture) or a Hill-Sachs deformity. On axial images, Hill-Sachs lesions are visualized in the posterolateral border of the humeral head at or superior to the base of the coracoid process. They must not be confused with the normal flattening of the humeral head, which is usually visualized more posteriorly and inferiorly but which may be found at the level of the coracoid in a patient with a large rotator cuff defect and superior translation of the humerus (Fig. 50-27).^{84, 163, 175, 216} In patients who have had a posterior dislocation, a “reverse” Hill-Sachs or trough lesion may be identified on the anteromedial margin of the head of the humerus in association with a posterior glenoid or labral abnormality.

Choice of Imaging Modality

MRI, CT arthrography, and MR arthrography all have roles to play in diagnosis of rotator cuff disease, impingement syndrome, and instability as well as other causes of shoulder pain. Furthermore, although not the topic of this chapter, conventional radiography, ultrasound, and conventional arthrography are also useful. Choosing the proper tool for each patient can be a daunting task, with no single, absolutely correct solution. We suggest that, in all patients, plain films of the shoulder should be the first imaging step. They may be sufficient. In young patients, they may reveal a fracture; in older patients they may disclose, with low sensitivity but as much as 98% specificity, a large rotator cuff tear.⁸¹ Spurs and other bony morphology associated with impingement syndrome may be appreciated. Conventional radiography can reveal calcific tendinitis and the erosions of rheumatoid arthritis.

Questions often remain after conventional radiographs

Figure 50-27. Hill-Sachs deformity. Proton-density-weighted (TR = 2500 msec, TE = 14 msec) axial image. At the level of the coracoid process (asterisk), a notch-shaped defect in the posterolateral humeral head (arrow) is typical of a Hill-Sachs defect. The patient had a history of recurrent anterior dislocation. Arrowheads indicate the coracohumeral ligament.

are obtained. The nature of the question and the age of the patient help guide the next choice.¹⁹¹ For instance, in a patient age 40 or older, in whom primary impingement syndrome and rotator cuff disease are suspected, MRI without intra-articular contrast is likely to provide accurate evaluation of the rotator cuff and a useful assessment of the labrum. In experienced hands, ultrasound may also assess the rotator cuff accurately and for less expense than MRI.

In a patient younger than 40 years of age, in whom instability is more likely to be a problem, either overtly or as a cause of impingement, it may be worth the extra expense and risk to use MR arthrography because of its improved depiction of the labrum. CT arthrography should probably be reserved for patients with contraindications for MRI.

Abnormalities of the Biceps Tendon Bicipital Tendinopathy or Rupture

Most cases of bicipital tendinopathy are the result of mechanical impingement that occurs with rotator cuff disease in middle-aged or older patients. With flexion of the shoulder, the tendon of the long head of the biceps may become closely approximated to the coracoacromial ligament and the anterior acromion, particularly in the presence of a rotator cuff defect, and may be compressed between these structures and the humeral head.^{33, 136, 154} This impingement eventually results in tendinopathy, with flattening and thinning of the tendon that may lead to complete rupture.^{128, 218} Bicipital tendinopathy can also occur in patients who have glenohumeral instability, particularly in the presence of pathologic conditions involving the superior labrum.

Early bicipital tendinopathy is often undetected on im-

Figure 50-28. Bicipital tendinopathy. *A*, T2-weighted axial image. Fluid surrounds the bicipital tendon within the groove. In addition, an abnormal focus of high signal intensity is present within the tendon (*arrow*). The anterolateral branch of the anterior circumflex humeral artery may be identified (*small arrow*). *B*, T2-weighted coronal oblique image. In this patient, as is commonly the case, biceps tendinopathy is associated with rotator cuff disease. A large tendon gap (*asterisk*) marks the location of a full-thickness tear of the supraspinatus muscle and tendon. (Courtesy of Timothy Greenan, M.D., Washington, DC.)

aging studies. Increased signal intensity within the abnormal tendon is rarely visualized on MR images (Fig. 50-28), but as in the rotator cuff tendon, it may be a result of the magic angle effect.⁴²

Morphologic abnormalities (e.g., fraying, flattening, absence of the tendon) may sometimes be identified, particularly within the bicipital groove. Fluid within the bicipital tendon sheath helps to delineate tendon morphology. The presence of fluid does not necessarily indicate bicipital tendon disease, however, because any fluid present often comes from the glenohumeral joint. Rarely, a disproportionately large amount of fluid is found within the biceps sheath compared with the amount within the joint; this should suggest bicipital abnormality.

Bicipital Tendon Dislocation

Bicipital tendon dislocation usually occurs in conjunction with large, long-standing tears of the rotator cuff that have extended to include the subscapularis tendon (Fig. 50-29). The tendon dislocation may be overlooked clinically because the symptoms are masked by the associated cuff tear. Other lesions necessary for bicipital tendon dislocation to occur include disruption of both the strong coracohumeral ligament, an important stabilizer of the biceps tendon,¹⁰⁵ and the weak transverse humeral ligament. In this setting, the tendon of the long head of the biceps dislocates medially, moving posterior to the subscapularis tendon and muscle and into the glenohumeral joint, where it may be mistaken for a detached anterior labrum. In rare circumstances, when the subscapularis tendon remains intact yet the coracohumeral and transverse humeral ligaments are disrupted, the biceps tendon displaces extra-articularly and anterior to the subscapularis muscle. Occasionally, the biceps tendon lodges within the fibers of the distal subscapularis tendon (Fig. 50-30).^{20, 21, 156}

Besides allowing identification of the displaced biceps tendon, both CT and MRI show an empty bicipital groove. On axial MR images, particularly those using gradient-echo sequences, tiny bony spicules projecting into the bicipital groove may mimic the biceps tendon. They may be distinguished from it, however, because they are probably not present on all the axial images where the biceps tendon would be expected to be seen. In addition, the far anterior coronal images also show an empty bicipital groove. Scar tissue within the bicipital groove may also resemble the tendon and mask a dislocation or tear.²⁰⁷

Surgery is usually performed in the young or middle-aged patient with dislocation of the biceps tendon. The tendon is replaced in the bicipital groove, and the fibrous

Figure 50-29. Bicipital tendon dislocation. Coronal reconstruction of an axial single-contrast CT arthrogram. The bicipital tendon (*arrow*) projects medial to the humeral head (*H*) in an intra-articular location. Contrast material extends through a gap in the supraspinatus tendon to outline the subacromial-subdeltoid bursa (*arrowheads*).

Figure 50-30. Bicipital tendon dislocation. Gradient-echo (TR = 600 msec, TE = 15 msec, flip angle = 70 degrees) axial MR image. The intertubercular groove is empty (arrow). The bicipital tendon is dislocated medially and lodged within the fibers of the subscapularis muscle and tendon (arrowhead).

roof is reconstructed. Tenodesis is not necessary unless the tendon is severely attenuated. Acromioplasty as well as rotator cuff arthroplasty can be performed. In older patients, the treatment is usually directed to the rotator cuff disorder; the biceps tendon dislocation is considered secondary.

Calcium Deposition Diseases

Hydroxyapatite deposition disease, including its manifestations as (1) calcific tendinitis or bursitis, (2) idiopathic destructive arthritis ("Milwaukee shoulder syndrome"), and (3) tumoral calcinosis, may all occur in the shoulder.

Calcific Tendinitis

Calcific tendinitis can involve most tendons, but it most commonly involves the supraspinatus tendon. Patients are typically in middle age, although the disease has been reported in a child as young as 3 years. Women are affected more commonly than men. The dominant shoulder is more likely to be affected. The cause is unknown, but calcific tendinitis is believed by some to be the result of calcification of metaplastic cartilage in the relatively ischemic distal supraspinatus tendon. The deposits may also extrude from the tendon into a bursa, usually the subacromial-subdeltoid bursa, producing calcific bursitis. The deposits may erode bone. Pain is the presenting complaint and seems to be correlated with fluffy, ill-defined deposits occurring with resorption rather than with the well-defined deposits more commonly seen in asymptomatic patients.^{112, 141, 203, 208}

Plain films are generally sufficient for the diagnosis.

Figure 50-31. Rheumatoid arthritis. T2-weighted (TR = 2500 msec, TE = 80 msec) coronal oblique MR image. High-signal-intensity and mixed-signal-intensity lesions in the humeral head contact the articular surface in other sections and probably represent deep erosions. Pannus at the periphery of the joint (short arrows) is lower in signal than the usual joint fluid and is slightly heterogeneous in signal.

The calcium deposits are also readily apparent on CT scans. If an MRI study is obtained, a small calcium deposit may be inapparent. Larger ones may appear dark because of immobile protons in calcium. If ossification has occurred and marrow is present in the deposit, the signal intensity matches that of other marrow. Bursal deposits have the same appearance as those in the tendons but are often accompanied by bursal fluid (Fig. 50-31).

Idiopathic Destructive Arthritis

Idiopathic destructive arthritis of the shoulder, or Milwaukee shoulder syndrome (named for the city where it was first described), is another calcium crystal-related abnormality. It is most often seen in elderly women. It is characterized by large, blood-tinged effusions containing calcium hydroxyapatite and by extensive destruction of cartilage and bone. It is often accompanied by derangement of the rotator cuff or the proximal tendon of the long head of the biceps brachii. The calcium-containing effusions distinguish it from simple rotator cuff arthropathy as does a tendency toward bilateral involvement and involvement of other joints, particularly the hips and knees.

The diagnosis of Milwaukee shoulder syndrome is generally made clinically. CT and MRI studies, if obtained, demonstrate the effusions and destruction of articular sur-

faces. CT may also demonstrate calcium deposition on synovial surfaces.^{64, 65, 108, 138}

Tumoral Calcinosis

In patients with tumoral calcinosis, amorphous, often liquid, deposits of calcium form near the joints, particularly the shoulder, hip, and elbow. The idiopathic form of the disease usually occurs in otherwise healthy young persons. There is a genetic component to this disease. It has been reported concurrently in siblings and has a predilection for blacks. The same term is often used for similar chalky deposits occurring in conjunction with systemic disease, usually chronic renal failure.

The diagnosis may be made by plain radiography along with history, physical examination, and laboratory studies. Neither CT nor MRI is usually necessary. Occasionally, however, the plain film appearance of such masses may be confusing and CT may help distinguish them from other calcified masses, such as chondrosarcoma and osteosarcoma.^{10, 23, 101, 116, 137} MRI, however, may be preferred for evaluating less intensely calcified masses.^{27, 43}

Rheumatoid Arthritis

Rheumatoid arthritis is a common disease with a predilection for women of middle age. The glenohumeral joint, the acromioclavicular joint, or both may be involved, but it is unusual for the disease to present in the shoulder before it has manifested elsewhere.^{28, 113}

In the glenohumeral joint, as elsewhere, rheumatoid arthritis is characterized by osteopenia, effusions, progressive loss of joint space, and osseous erosions. The effusions may cause outpouchings of the synovium; when very large they are termed giant synovial cysts. Acromioclavicular involvement has a similar appearance, except that the scapula and clavicle are held in their respective locations by

surrounding structures and do not migrate closer to one another with destruction of the joint surfaces. Thus, the acromioclavicular joint space widens rather than narrows with rheumatic involvement.^{28, 113}

Inflammatory arthritides, especially rheumatoid arthritis, predispose the patient to tendon and ligament ruptures. In the shoulder, they may lead to rotator cuff tears.

Rheumatoid arthritis may be identified by clinical and serologic means. Radiographic techniques are less useful in diagnosis than in plotting progression of disease and response to therapy. MRI is more sensitive than plain films to the presence of effusions and small erosions and may directly depict pannus (Fig. 50–32). Use of intravenous gadolinium helps to distinguish pannus from effusions. Both may appear low in signal intensity on unenhanced T1-weighted images and high in signal intensity on T2-weighted images, but pannus enhances. Therefore, MRI may have a role in evaluating therapeutic response. Most likely, however, the hands and wrists will be a more fruitful site of evaluation than will the shoulder.^{6, 50, 167, 211}

Pigmented Villonodular Synovitis

Pigmented villonodular synovitis (PVNS) is an uncommon disorder of unknown cause. It usually affects young adults and is typically monoarticular, with most frequent involvement of the knee. It is rare in the shoulder.^{37, 48, 179} Histologically, PVNS demonstrates fatty areas together with hemosiderin deposition. This results in a heterogeneous appearance on both CT scans and MR images. On MR images, the hemosiderin creates areas of decreased signal intensity on intermediate weighting. The signal intensity decrease becomes more prominent on T2 weighting. On gradient-echo imaging, the paramagnetic affect of hemosiderin causes even more dramatic signal loss. Effusions may be present.^{15, 77, 88, 92, 104, 189} One case that involved the shoulder is reported to have had very little hemosiderin on histologic study and to have demonstrated on MR images

Figure 50–32. Calcific tendinitis. *A*, Gradient-echo axial image. A large area of signal void (arrow) is present near the attachment site of the supraspinatus tendon. *B*, Proton-density-weighted (TR = 2500 msec, TE = 14 msec) coronal oblique image. Signal void is present in the relatively avascular area of the supraspinatus tendon (arrow). This area was also dark on T2-weighted images. Calcium was apparent by plain films (not shown).

Figure 50-33. Spinoglenoid notch lipoma. T1-weighted (TR = 500 msec, TE = 14 msec) sagittal oblique image. A homogenous mass (asterisk) of fatty signal intensity in the spinoglenoid notch is typical of a lipoma. Its signal parallels that of fat on other pulse sequences as well.

none of the signal dropout usually ascribed to hemosiderin.¹⁷⁹

Neurogenic Shoulder Dysfunction Suprascapular Nerve

Pressure on the suprascapular nerve as it courses across the posterior scapula is an uncommon cause of shoulder

pain. Any mass that arises in an appropriate location can produce suprascapular nerve entrapment; reported causes include neoplasms and hematoma (Fig. 50-33). The most common cause, however, is a ganglion cyst. These cysts usually occur in young men. They typically arise from a labral tear in much the same fashion that a meniscal cyst arises from a torn meniscus.^{194, 209} Ganglion cysts may occur at various sites about the shoulder, but those causing suprascapular nerve compression usually occur at the spinoglenoid notch. They may extend superiorly into the supraspinatus fossa or inferiorly into the infraspinatus fossa. They may produce muscle paralysis and atrophy as well as pain. The infraspinatus muscle is most often affected, but the supraspinatus muscle may be involved as well.

Ganglia may be detected as a water-density mass by CT. On MR images, they are approximately isointense with muscle on short TE images and very bright on T2-weighted images. If intravenous Gd-DTPA is administered, the cysts may enhance about their rim. They often appear septate. Muscle atrophy, if it has ensued, may also be apparent on the MR image; the earliest sign of denervation atrophy is increased signal intensity on T2-weighted images within the involved muscle. In three reported cases, CT-guided aspiration yielded relief. In other cases, patients have successfully undergone surgery, and occasionally such cysts have resolved spontaneously (Fig. 50-34).^{52, 144} When the cyst arises from a labral tear, the tear must be addressed.^{194, 209}

Suprascapular nerve dysfunction may also be caused by direct injury to the nerve. One reported case was associated with a previous clavicular fracture. MRI assisted in the diagnosis by demonstrating abnormally high signal intensity on T2-weighted images in the belly of the supraspinatus and infraspinatus muscles.²¹⁷

Acute Brachial Neuritis

Acute brachial neuritis, or *Parsonage-Turner syndrome*, presents with a sudden onset of intense, burning shoulder

Figure 50-34. Spinoglenoid notch ganglion. A, T2-weighted (TR = 2500 msec, TE = 70 msec) sagittal oblique image. A single, rounded, hyperintense mass (asterisk) is present in the spinoglenoid notch of this young man who presented with shoulder pain. B, Gradient-echo axial image. At this level, the lesion is composed of multiple smaller masses. On proton-density images, this mass was intermediate in signal, approximately isointense with muscle. This location and appearance are typical of a spinoglenoid notch ganglion.

pain and muscle weakness, most commonly involving the supraspinatus and infraspinatus muscles, although other shoulder muscles may be involved as well. The patients are most typically young to middle-aged adults. There is a marked male predominance. This is a self-limited disease, with resolution first of the pain. Muscle weakness may last years but usually resolves in 2 to 3 months. MRI may reveal increased signal intensity in the involved muscles on T2 weighting. Later in the course of the disease, muscle wasting without fatty infiltration may be evident. MRI is chiefly useful in excluding other causes of shoulder pain and dysfunction, particularly compressive masses in the spinoglenoid notch.⁶⁹

Quadrilateral Space Syndrome

Another cause of shoulder pain and dysfunction is quadrilateral space syndrome, in which the axillary nerve is compressed by fibrous bands as it traverses the quadrilateral space. This space is bounded by the teres minor and teres major muscles, the long head of the triceps muscle, and the surgical neck of the humerus. It manifests clinically with poorly localized shoulder pain, lateral shoulder and posterior upper arm paresthesias, and weakness and atrophy of the teres minor and/or deltoid muscles. MRI does not show the actual entrapment but may demonstrate denerva-

tion atrophy of the appropriate muscles and exclude other causes of shoulder pain.⁹⁸

Angiography has been used to confirm the diagnosis on the basis of occlusion of the posterior humeral circumflex artery with the arm in abduction. In 1994, Mochizuki and coworkers cast doubt upon the usefulness of this approach or, more specifically, of using MR angiography in place of conventional contrast angiography, when they found that MR angiography demonstrated occlusion of 80% of the posterior humeral circumflex arteries of six asymptomatic volunteers with abduction.¹¹⁹

Trauma

Most fractures about the shoulder are adequately evaluated with plain radiography. In cases of complex fractures of the proximal humerus, CT may be helpful for pretreatment planning. Treatment of these fractures varies considerably, depending on their position in the widely used classification scheme of Neer.¹²⁷ This scheme is based on the degree of separation or rotation of the four possible major fracture fragments (shaft, head, greater tuberosity, and lesser tuberosity). A fragment is considered displaced if it is distracted 1 cm or more from its neighbors or if it is angulated 45 degrees or more from its proper location.¹²⁷

Fractures without displacement are commonly treated with early mobilization, whereas those involving displace-

Figure 50-35. Humeral fracture. A, Plain film. The humerus has been fractured. A crescent of bone typical of a detached greater tuberosity projects superolateral to the humeral head. B, Axial CT scan demonstrates more graphically, compared with plain film, the amount of damage that has occurred to the region of the greater and lesser tuberosities. C, This 3D reconstruction shows the relationship of the detached greater tuberosity (white arrow) to the remainder of the humerus. A, acromion; C, clavicle. (Courtesy of Stein Rafto, M.D., Honolulu.)

ment of one of the tuberosities often require open reduction. It is important, therefore, to determine accurately the position of all fragments before definitive treatment is carried out. This may be difficult with plain radiographs alone.

Castagno and colleagues found that in 12 cases of acute fractures and five cases of persistent limitation of motion after treatment of fracture, CT provided useful information that was not evident on plain film.¹⁹ Even when the information is available on the plain films, evaluation of fragment location may be difficult, as evidenced by reports of high interobserver variability in classifying humeral fractures according to Neer's scheme. Furthermore, CT may be useful because it can provide a much more graphic depiction of fragments, particularly when 3D reconstruction is available. In addition to localizing major fracture fragments, CT can locate smaller ones; this is particularly useful for intra-articular fragments. Loose bodies of non-traumatic origin may also be located with CT, of course (Fig. 50-35).^{19, 70, 86, 93, 130}

CT may be used to detect complex scapular fractures. These are rare injuries, usually seen in patients who have sustained multiple injuries as a result of direct, blunt trauma, often an automobile accident. These fractures may be missed on initial plain radiography, particularly on the portable chest films often obtained on patients who have sustained severe trauma. When a suspected scapular fracture has not been revealed on such a film, it may be easier as well as more diagnostically rewarding to obtain a CT study rather than plain films of the shoulder.^{1, 67, 110, 192}

CT may also be useful in evaluation of scapular fractures. Treatment of scapular fractures is less well established than treatment of humeral fractures. Some surgeons believe that displaced fractures of the glenoid and scapular spine should receive internal fixation; others suggest that these injuries, like other scapular fractures, may be satisfactorily treated by immobilization, followed by range-of-motion exercises shortly thereafter. In addition, the patient's other injuries may preclude surgical intervention. When treatment hinges on the site of the fracture and the degree

Figure 50-37. Occult fracture. Gradient-echo axial image. The low-signal-intensity line oriented perpendicular to the articular surface of the glenoid (arrow) is a fracture line and represents a reverse bony Bankart lesion. The patient had a history of posterior dislocation. The posterior capsule has also been stripped from the glenoid neck, leaving an inhomogeneous collection of subperiosteal hematoma and/or granulation tissue (arrowheads).

of displacement, however, CT may be more easily obtained and more revealing than plain films (Fig. 50-36).^{1, 111}

MRI may reveal occult fractures, which appear as a line of abnormal signal intensity extending through cancellous bone to reach a cortical surface (Fig. 50-37). MRI may demonstrate the anterior-inferior labral tear and associated

Figure 50-36. Glenoid fracture. A and B, Axial CT scans. Extension of this fracture to the articular surface of the glenoid is easily appreciated at CT.

Figure 50-38. GLAD (glenolabral articular disruption) lesion. Gradient-echo axial MR arthrogram. Gadolinium tracks between the anterior labrum and the glenoid and extends medially to the neck of the glenoid, indicating an avulsion of the anterior-inferior labrum (arrow). Abnormally increased signal is also present in the articular cartilage, indicating the cartilaginous injury found in this constellation of associated abnormalities (small arrow).

articular cartilaginous injury typical of the *glenolabral articular disruption* (GLAD) lesion. This combination of injuries is not associated with dislocation or instability; rather, it is an impaction injury caused by the humerus being driven forcefully into the glenoid (Fig. 50-38). Acute trauma may also cause a rotator cuff tear, particularly when superimposed on preexisting degeneration. The tear may be evaluated on MRI using the same criteria discussed previously for tears not related to trauma.

Summary

There is little doubt that CT, MRI, and CT and MR arthrography accurately reveal anatomic defects in the shoulder. Less research has focused on the usefulness of the information. Blanchard and colleagues in 1996 found that MRI led to new diagnoses in 20 (34%) of 59 patients. For 25 of the 52 unchanged diagnoses (some patients had more than one diagnosis), MRI increased the referring physician's confidence in the diagnosis.¹¹

For any of these modalities to be maximally effective in a patient's care, however, there must be careful correlation between clinical presentation and imaging results, a task that largely rests on the shoulders of the referring physician. In 1995, Sher and coworkers discovered a 34% prevalence of MRI findings of rotator cuff tear in asymptomatic individuals. The frequency of these presumed tears increased with age.¹⁷⁸ To optimize imaging for individual

patients, it is also important to remember the contributions that can be made by plain films, arthrography, and ultrasound.

Acknowledgments

We would like to thank Kim Slonaker for her patient and precise word processing and Cheryl Bost for photography.

Computed Tomography and Magnetic Resonance Imaging in the Pediatric Patient: Special Considerations

Donald P. Frush

Children present unique challenges for computed tomography (CT) and magnetic resonance imaging (MRI). Although it is well recognized that the type and frequency of disorders differ between children and adults, it is less often apparent that there are also important considerations for performing CT and MRI.²³ These technical considerations are a critical component of the examination, as adequate (and preferably optimal) images are requisite for interpretation.

This chapter focuses on technical aspects of CT and MRI when used for neonates, infants, and children, especially on those features that are common to both modalities. Emphasis is placed on technical aspects that either differ from or are not addressed in the chapters on adult CT and MRI. Aspects that differ between modalities are covered in other chapters.

General Technical Considerations

CT and MRI examinations of children share several technical issues, including the need for sedation, the potential for movement artifacts, and the smaller anatomy. In addition, the wide range of sizes in the pediatric population, from under 1.0 kg to the weight of a large adult, requires the radiologist to be familiar with a greater variety of technical modifications than those needed in the adult population. For this reason, the concept of protocols is less applicable in children than in adults. Although protocol imaging can be performed at times, the radiologist should realize that alterations in scan preparation and parameters may be necessary.

The first issue to address in cross-sectional imaging is the indication of the study. It may be that another imaging technique, such as sonography, would give sufficient information, obviating the use of greater resources (e.g., sedation, intravenous [IV] or oral contrast material), scheduling

difficulties, and expense. Once it has been determined that either CT or MRI is appropriate, attention can be directed to the technical considerations.

Reduction of anxiety (for both children and parents) is an important aspect of pediatric imaging.^{8, 22} In a number of centers, child-friendly environments both inside and outside the scanning area provide a more pleasant experience. Examination preparation includes instructions about nil per os (NPO) instructions if sedatives are to be used. This prevents having to reschedule the examination, which can be a great inconvenience for the family. At the time of the examination, written material, videotapes, or digital media explaining the procedure can reduce anxiety and uncertainty. Discussion with the technologist (or other radiology staff) gives family members an opportunity to ask questions about the procedure. Because the parent is usually essential in helping a child adjust to a potentially threatening environment in the CT or MRI suite, this pre-examination preparation is extremely important. Some centers have found success with models of scanners, which allow the child to become familiar with the appearance of the scanners and aspects of the physical environment.

One of the most important technical facets in cross-sectional imaging modalities is sedation. Several comprehensive reviews on the sedation of children for diagnostic radiology are available.^{8, 14, 20-22} The following text emphasizes the salient aspects.

Although both CT and MRI examination times have decreased with the advent of newer technology, sedation remains an unavoidable aspect in imaging children. The general principles and guidelines for pediatric sedation were published several years ago^{2, 10, 28} and have resulted in a substantial change in the way in which sedation for diagnostic imaging is performed.^{20, 22, 42} The basic tenet is to protect the welfare of the child. To do this, it is vital to adhere to a minimal set of standards,^{10, 28} which include:

- Presedation evaluation (i.e., history and physical examination)
- Selection of agents from a standard compendium of agents used in diagnostic imaging (Table 51-1)
- Procedural monitoring
- Adherence to strict discharge criteria

Various agents have been used successfully and safely for sedation in infants and children (see Table 51-1). Although multiple sedatives and combinations of agents are available, a successful sedation program makes use of a relatively small subset of proven agents with which the radiologists is familiar. Used as part of an appropriate sedation program, these agents should provide successful sedation in more than 95% of children.^{14, 22} Sedatives are not always safe, and their administration does not guarantee success. To this end, newer agents continue to be introduced (e.g., propofol, ketamine), and new combinations of agents are promoted for use in diagnostic imaging.

No single agent or combination of agents is perfect. Sedation in pediatric imaging will become an insignificant issue only when imaging is nearly instantaneous, such as with radiography. Faster MR sequences have not had the same impact on sedation that the faster technology of helical and multislice helical CT scanning has had. The rate of sedation for children dropped from about 18% to 10% as helical CT replaced the incremental slice-by-slice scanning.^{30, 44} Multislice helical CT technology has further reduced the rate of sedation to about 3% in children younger than 6 years of age.³⁴ Alternatives to sedatives include feeding young infants immediately prior to examination, reduction of anxiety in older children and adolescents, and pain management.^{8, 22}

Choral hydrate and sodium pentobarbital are two of the most commonly employed sedatives in pediatric diagnostic imaging.^{14, 22} Choral hydrate is generally given orally in doses of 50 to 100 mg/kg of body weight (maximum dose, 2.0 g). This dose is most successful in infants younger than 1 year of age. IV sodium pentobarbital is another very successful agent and is safe when used appropriately. The dose is given in titrated amounts of 1.0 to 3.0 mg/kg to a total dose of 6.0 to 8.0 mg/kg (maximum dose, 200 mg).

Occasionally, fentanyl citrate in titrated doses of 1.0 µg/kg (maximum dose, 4.0 µg/kg) can be used in conjunction with pentobarbital in children who are more difficult to sedate or need some analgesia in addition to sedation. For CT-guided or MRI-guided interventional procedures, midazolam 0.02 to 0.05 mg/kg (maximum initial dose, 1.0 mg; subsequent doses titrated to effect) is useful in conjunction with fentanyl. The combination of fentanyl citrate and sodium pentobarbital is usually more successful in children younger than 8 years of age for CT interventional procedures.

Specific Technical Considerations

Computed Tomography

Technical parameters to be considered in designing appropriate CT examinations for children include breathing techniques, oral or IV contrast agents, and the scanning parameters, such as tube current and factors affecting pitch.

Attention to these specific parameters is imperative in order to perform an optimal examination while minimizing potential risk to the child. Such risks include (1) excessive radiation exposure (e.g., from rescanning because of poor technique), (2) the need for additional IV contrast media, and (3) inappropriate use of oral contrast materials. General recommendations for parameters in chest, abdomen, and pelvis helical CT scanning are presented in Tables 51-2 and 51-3.

Breathing Strategies

Breathing strategies, usually standard for adult helical CT scanning, depend on the age of the child. After a child is about 8 years old, scan durations of 20 to 30 seconds can be performed during a breath-hold. Before that time, the ability to breath-hold remains relatively limited, although it is worth attempting a trial. However, trials may be unreliable because of the potential unpleasant sensations of IV contrast administration, noise, and movement of the table and scan gantry during the procedure. During CT of the chest and abdomen and during CT angiography, it is often best to simply have the young child breathe quietly to avoid the risk of nonperiodic respiratory motion, which would diminish scan quality. Breath-holding is not necessary during pelvic scanning.

Oral Contrast Material

Gastrointestinal (GI) contrast material can be given in several ways. Oral administration generally refers to methods of giving contrast media by mouth or through tubes into the upper GI tract. Rectal administration via a rectal tube can also be useful but is not routine. Although GI contrast material is often considered routine for adults, administration in children can be more difficult, can pose risks (although rarely) and either may be unnecessary or may adversely affect diagnosis.

Recommended amounts of oral contrast material for children of different ages are listed in Table 51-4. Agents usually consist of water-soluble contrast diluted with a clear liquid beverage, such as a fruit drink or a carbonated soft drink. Barium solutions are also available. Other oral contrast agents should be considered for pediatric CT. For example, water is sometimes helpful in opacification of the upper GI tract (Fig. 51-1). Air may be a sufficient intrinsic luminal contrast agent in the setting of an ileus, or fluid and air, in the case of an obstruction. In one review of CT techniques, whole milk has been suggested as an agent because the fat is thought to slow bowel peristalsis.¹⁹

The advantage of orally administered contrast agents is primarily opacification of the hollow viscous, which provides information on course, caliber, lumen and wall, and separation from subjacent structures; however, contrast material is not always necessary. For example, evaluations of the liver, adrenal glands, and kidneys do not mandate opacification of bowel.

There are also disadvantages with these agents. It can be difficult to get young children to drink. Taking fluid by mouth prior to sedation increases the risk of aspiration in children who need sedation for a CT scan.^{2, 22} Oral contrast material can be considered an important component of a CT scan and is not contraindicated in this setting.^{20, 22} GI

Table 51–1. Sedative Agents for Pediatric Imaging

Agent	Class	Effect	Dose	Route*	Onset	Duration†
Chloral hydrate‡	NA	Sedative	50–100 mg/kg, up to 120 mg/kg reported, max single dose 2 g	PO (PR)	20–30 min (rarely, up to 60 min)	30–90 min
Sodium pentobarbital	Barbiturate	Sedative	2–3 mg/kg doses titrated q 5–7 min until sedated or max cumulative amount of 8 mg/kg, not to exceed 200 mg	IV (PO, IM)	5–10 min	40–60 min
Fentanyl citrate	Narcotic	Analgesic with sedative properties	1 µg/kg slowly IV q 5–7 min, adult-sized patients 25–50 µg per dose, max cumulative dose 4.0 µg/kg	IV	1–2 min	30–60 min for analgesia; sedation may be shorter
Midazolam	Benzodiazepine	Sedative, anxiolytic, amnestic	0.02–0.05 mg/kg IV, titrate using ½ original dose (2–4 min) based on effect and oxygen saturation, max bolus dose 1.0 mg	IV (PO)	1–5 min (IV)	20–30 min
Diazepam	Benzodiazepine	Sedative, anxiolytic, amnestic	0.05–0.1 mg/kg IV, max cumulative dose 5.0 mg; 0.2–0.3 mg/kg PO, max cumulative dose 10 mg	IV (PO)	5–15 min (IV)	30–120 min
Methohexital	Barbiturate	Sedative	20 mg/kg in 10% solution	PR	10–15 min	45 min
Morphine	Narcotic	Analgesic with sedative properties	0.1–0.2 mg/kg, max dose 3–4 mg	IV (IM)	3–5 min	Analgesia up to 4 hr; sedation is variable but shorter
Meperidine	Narcotic	Analgesic with sedative properties	1–2 mg/kg, max dose 100 mg	IV (IM)	5–10 min	Analgesia 1–2 hr; sedation is variable but shorter
Naloxone hydrochloride	NA	Narcotic antagonist	0.01–0.1 mg/kg (lower antagonist dose for infant); repeat 2–3 min; titrate to reversal, max dose 2 mg	IV	1–2 min	Max to 20–30 min
Flumazenil	NA	Benzodiazepine antagonist	0.01 mg/kg, max dose (adult) 0.2 mg, max cumulative dose 1 mg	IV	1–3 min; peak effect 6–10 min	Max 60 min but usually <30 min depending on benzodiazepine dose

IM, intramuscular; max, maximum; NA, not applicable; PO, per os (orally); PR, per rectum.

*Preferred route listed first, with alternate routes in parentheses.

†Duration of sedative effect for imaging purposes. Drowsiness, ataxia, and other effects may have variable durations depending on the agent, dose, and route of administration.

‡Thioridazine or hydroxyzine have been reported as adjuncts in children difficult to sedate with chloral hydrate alone.

From Frush D: Pediatric sedation in radiology: The practice of safe sleep. Am J Roentgenol 167:1383, 1996.

Table 51–2. Recommendations for Pediatric Chest Helical CT Scanning

	≤4 yr	5–8 yr	9–12 yr	>12 yr
Scan Parameters				
kVp	120–140	120–140	120–140	120–140
mAs (suggested)*	25–100	50–125	50–150	50–175
Collimation (mm)	3–5	5	5–7	5–7

Table 51-4. Oral Contrast for Abdominal and Pelvic CT in Infants and Children*

Age	Amount†
1-6 mo	60-120 mL (2-4 oz)
6-12 mo	120-180 mL (4-6 oz)
1-4 yr	180-270 mL (6-9 oz)
4-8 yr	270-360 mL (9-12 oz)
8-12 yr	360-480 mL (12-16 oz)
12-16 yr	480-600 mL (16-20 oz)
>16 yr	Adult volume

*45-90 minutes before examination.

†1.5%-3.0% solution; consider giving an additional amount equal to one half of original volume 15 minutes before scanning.

From Frush DP: Pediatric helical CT: Techniques and applications. Med Imaging Int 9:12-18, 1999.

tract contrast material may mask subtle mucosal enhancement (e.g., in inflammatory, infiltrative, or ischemic bowel disease), may mask an intraluminal or submucosal hematomia (e.g., in the setting of trauma or bleeding diathesis),¹² or may hinder three-dimensional (3D) reconstructions used for CT angiography. Although oral contrast for trauma patients is generally safe,^{16, 32} the risk of aspiration needs to be considered.¹³

Oral iodinated media and barium are other contrast agents. A similar concentration of iodine as given orally can be given via a rectal tube and is generally tolerated in young infants (who are not sedated) and in children older than about 4 years of age. For children between infancy and 4 years of age, enemas often cause agitation and can arouse a sedated child. Rectal contrast administration should be used as a problem-solving tool when one is evaluating unclear processes adjacent to the colon or in the lower abdomen or pelvis. In particular, retrograde colon opacification may help in the definition of bowel from an adjacent inflammatory process such as an abscess (Fig. 51-2).

Intravenous Contrast Material

A critical aspect of chest, abdomen, and pelvis CT scanning in children is administration of IV contrast mate-

rial. Among the many challenging variables in pediatric scanning are the small contrast volumes, the location and caliber of IV catheters, the method of injection, and the unpredictable physiologic factors.²⁶ Despite these challenges, attention to each facet of IV contrast technique can result in excellent contrast-enhanced CT scans in almost every instance.

In general, although low-osmolar, nonionic agents are recommended for scanning in children,⁹ choices must be made on the basis of pertinent practice standards. The dose of contrast material is generally 2.0 mL/kg (up to an adult dose of about 150 mL), although higher amounts, up to 3.0 mL/kg,³⁸ have been advocated. Smaller amounts have been advocated in adults^{18, 40} but have not been systematically tested in children. However, because organ and vessel enhancement depends on the amount of iodine delivered, there is a threshold amount at which opacification is suboptimal. One study has shown sufficient although significantly reduced enhancement of the liver in children with a dose of 1.5 mL/kg of iodinated contrast material at an iodine concentration of 300 mg/mL.²⁵

For chest scanning, in which opacification of vascular structures (not organ enhancement) is the goal of IV contrast material, doses of about 1.5 mL/kg can be used successfully.^{23, 45} For CT angiography in children, doses vary from about 1.5 to 3.0 mL/kg.²⁴

The rate of contrast administration varies with the caliber of the angi catheter and the method. Rates of about 2.0 mL/second are recommended for overall scanning. Higher rates can be used in adolescents (e.g., 3.0 mL/second). Rates as low as 1.0 mL/second have provided good enhancement of abdomen viscera.²⁶

Manual administration of contrast medium results in an unpredictable rate. In general, the rates of manual administration vary between about 1.0 and 3.0 mL/second, with an average in most injections of about 2.0 mL/second.²⁴ Power injectors have been used with increasing frequency in the pediatric population.²³ Suggested rates are 1.0 to 1.5 mL/second for 24-gauge angi catheters and 1.5 to 2.0 mL/second for 22-gauge angi catheters.²³

The complication rate with power injection of contrast material does not differ from that with manual administration when the angi catheter functions well and the site is

Figure 51-1. Malignant sacrococcygeal germ cell tumor in a 1-year-old girl. Surveillance CT examination was performed to evaluate for metastatic disease. Because the child refused to drink contrast media, a fruit-flavored clear liquid was administered in place of iodinated contrast material. Note the excellent delineation of the small-bowel loop (arrows) in the pelvis. The small bowel and the large bowel were also well visualized in the upper abdomen (not shown) as a result of a combination of intraluminal fluid and gas.

Figure 51-2. Complicated appendicitis in a 3-year-old girl. *A*, Axial CT scan at the level of the upper pelvis following administration of oral and intravenous contrast material. There are several interloop abscesses (*arrows*). More anteriorly, it was difficult to distinguish intestine from inflammatory change. *B*, After administration of 360 mL of rectal contrast material, it is clear that colon occupied the region in question. There were no abscesses that were amenable to percutaneous drainage.

monitored during injection. The use of contrast power injectors with central venous catheters is more controversial, although the reported rate of complications is also low.²⁹ The practice of power injection of contrast material through central lines is probably more common than reported in the literature.²³

With the advent of helical CT, techniques for the initiation of contrast-enhanced scanning have changed. With conventional or incremental abdomen scanning, imaging was initiated after approximately half of the bolus was administered, and it continued throughout the remainder of the scanning of the liver. With helical CT scanning, nearly all investigators recommend that scanning of the abdomen should begin after the administration of contrast material is complete (Table 51-5).

Recommendations for the delay from the end of contrast administration to the beginning of scanning vary from about 3 to 30 seconds. With multislice technology, image acquisition is many times faster than with a standard helical scanner, and new demands are placed on the technique of administration. If scanning is initiated too early, all imaging would be completed before optimal or desired enhancement is obtained. Recent work with multislice scanners has indicated that a delay of 20 seconds,²⁵ in line with delays recommended in some previous studies^{26, 40} for the helical

CT scanner, results in excellent enhancement of intra-abdominal structures in children.

In addition to the empirical delays just noted, a number of CT manufacturers offer bolus-tracking technology. With bolus tracking, serial low-dose, isolevel slices are obtained rapidly and sequential enhancement is displayed (Fig. 51-3). When the desired organ or vessel enhancement is obtained, diagnostic scanning is initiated. In this way, scanning can be individualized. This technology can be useful when pediatric scanning is infrequent and empirical methods for initiating the scan are less familiar or in complex cases when the time until optimal enhancement is uncertain.²⁶ In particular, CT angiography in young infants can achieve excellent results using bolus-tracking technology.²⁴

In addition to GI and IV contrast administration, a variety of other parameters must be thoughtfully selected for pediatric CT, including tube current (in mA) (Fig. 51-4), kilovoltage, collimation, table speed, and reconstruction interval. Recommendations for collimation and pitch are listed in Tables 51-2 and 51-3.

In general, most routine chest, abdomen, and pelvis scans can be obtained at a pitch of 1.5. Pitches up to 2.0 may be used to study, for example, abscesses, small-bowel obstruction, or follow-up examinations for trauma. With new multislice technology, the concept of pitch is more

Table 51-5. Pediatric Contrast-Enhanced Abdominal Helical CT: Recommendations for Initiation of Diagnostic Scanning

Investigator	Injection	Rate	Delay*
White ⁴³	Manual	—	10–20 sec
Luker et al ³³	Power	1.2 mL/sec	130% of injection duration
Roche et al ³⁶	Power	1.7–2.0 mL/kg/min	60–70 sec from onset of contrast injection
Ruess et al ³⁸	Power	2.0 mL/sec	10–12 sec
Frush et al ²⁶	Manual	0.3–3.5 mL/sec	Mean, 29 sec

*Delay from end of contrast injection unless stated otherwise.

From Frush DP: Pediatric helical CT: Techniques and applications. Med Imaging Int 9:12–18, 1999.

Figure 51-3. Value of bolus-tracking technology in a 14-day-old male infant. The rate of contrast administration (manual injection via a 24-gauge angiocatheter in the hand) was 0.25 mL/sec. A, Bolus-tracking technology displayed on the CT monitor includes the baseline unenhanced image of the liver (upper left), final image in the series (upper right), and graphic (lower left) and tabular (lower right) display of actual hepatic enhancement. A region-of-interest cursor was placed on the liver. Diagnostic scanning was initiated once hepatic enhancement surpassed 50 Hounsfield units (arrow). Each of the seven images obtained during bolus tracking (one baseline precontrast image and six postcontrast monitoring images) was obtained at 8 mA. B, Axial contrast-enhanced CT scan near the level of the confluence of the hepatic veins demonstrates excellent enhancement of the liver parenchyma, hepatic veins, and aorta.

Figure 51-4. Low-dose CT scanning in an 8-year-old boy seen in the emergency department for possible appendicitis. A, Axial CT scan obtained through the pelvis without oral or intravenous contrast material was obtained initially at 100 mA. These are multiple fluid-filled loops of small bowel in addition to thickening of the terminal ileum (arrow) due to Crohn's disease. The appendix (small arrow) was normal. B, Subsequent CT images were obtained through the pelvis because an artifact was present in the initial series. The image from a level similar to that in A but obtained at 30 mA shows no substantial difference in diagnostic information. (Courtesy of Ithaca Center for Postgraduate Medical Education, Ithaca, NY, 2001.)

complex. Depending on the detector array, higher pitches (e.g., 6.0) are now possible, with even faster scanning on the horizon as a greater number of detectors become available.

Increasing tube current provides increased spatial resolution because of an increased signal-to-noise ratio, but a higher radiation dose results. The optimal range of tube currents has not been determined for body scanning in infants and children, but probably much of pediatric helical CT is performed using too great a tube current. For example, one review of 55 CT scans from a variety of practices revealed that the mean dose for body CT in children was nearly 200 mAs,^{34a} more than is recommended for children^{23, 45} and occasionally for adults.⁴⁵ Some data on chest scanning in both adults¹¹ and children^{1, 37} have shown that low tube current in the range of 25 to 50 mAs yields acceptable diagnostic quality. In addition to lower tube current, the use of higher pitches (1.5 to 2.0) imparts less radiation than a pitch of 1.0 (when all other parameters are kept constant), with no loss in diagnostic quality.⁴¹ Therefore, until definitive recommendations are available, it is prudent to consider lower tube currents and higher pitches for pediatric CT (see Tables 51-2 and 51-3).

Pediatric CT angiography has only recently been addressed in children.²⁴ The technique is difficult because of the need for rapid scanning during peak vascular enhancement. Again, small patient size and smaller total dose, small-gauge angiocatheters, relatively remote locations (i.e., hands and feet), uncertain injection rates with manual injection, and small vessel anatomy make CT angiography in children challenging. Nevertheless, adequate pediatric CT angiography can be performed (Tables 51-6 and 51-7).

Table 51-6. Pediatric CT Angiography: Technical Problems and Potential Solutions

Problem	Solution
Small patient size (small contrast volume)	Increase dose up to 3.0 mL/kg Dilute contrast (e.g., 3:1 with normal saline) Faster scanners (dual and multiple detector row)
Large area of coverage	Increase dose up to 3.0 mL/kg Dilute contrast (e.g., 3:1 with normal saline) Increase table speed Faster scanners (dual and multiple detector row)
Unable to breath-hold	Quiet respiration General anesthesia with suspended respiration Faster scanners (dual and multiple detector row)
Small-caliber IV	Power injector at rates 1.2–2.0 mL/kg (24 gauge); 1.2–2.5 mL/kg (22 gauge)
Scan initiation	Bolus tracking Test bolus in larger children Empirical delay of 5–20 sec after beginning of contrast administration (the shorter delay for young children, or central venous catheters); longer delays may be necessary for foot angiocatheters
Small-vessel anatomy	Narrow collimation and reconstruction interval
Unable to hold still	Sedation

Table 51-7. Steps for Pediatric CT Angiography

1. Determine or estimate breath-holding ability (generally 5–30 seconds).
2. Determine length of coverage.
3. Calculate table speed for which scan can be completed during breath-hold (length of coverage/breath-hold duration) or peak vessel enhancement (less than duration of injection—see below), whichever is shorter. Use the minimum collimation that gives appropriate pitch (e.g., 1.5–2.0 with single-array detector scanner).
4. Peak vessel enhancement.
 - a. Select IV contrast material dose (2.0–3.0 mL/kg).
 - b. Select rate of contrast administration (power injector 1.2–4.0 mL/sec); manual injection rate needs to be estimated (range, 1.0–2.5 mL/sec).
 - c. Calculate (or estimate if manual injection) duration of injection (IV contrast is started prior to diagnostic scanning and should finish before scanning is completed).
 - d. Adjust rate, volume (e.g., consider dilution or increasing total dose), or table speed so that contrast administration is completed shortly before the end of scanning.
 - e. Scan onset. Use test bolus (larger children), bolus tracking, or empirical delay. Empirical scan onset determined by adjusting table speed, collimation, rate, and volume such that scanning begins with a minimum delay of 5 to 20 seconds after beginning contrast (short delays with small total volumes of contrast, central venous catheters; long delays with lower extremity venous access).

Magnetic Resonance Imaging

Some technical aspects of pediatric MRI differ from those of CT scanning. Moreover, the types of sequences performed and the parameters for each sequence vary to a greater degree (and are evolving more rapidly) than in CT scanning. For these reasons, a more general discussion of MRI techniques is appropriate (see other chapters that discuss MRI for organ systems and specific disease processes in adults and children). The text here addresses general techniques that apply to MRI across organ systems and that are unique to pediatric MRI.

The greatest technical hurdle in children is motion artifact, which is caused either by periodic or physiologic motion (cardiovascular pulsation, respiration) or by random motion (including peristalsis and musculoskeletal movement). Periodic motion causes ghosting artifact, whereas image blurring results from random motion.

Several useful strategies can minimize or prevent the artifacts associated with random motion in children. Sedation has already been discussed. Because of longer MRI times, children require sedation more often than they do for CT,⁵ but children older than 7 years do not routinely need sedation. Children younger than 7 years may not need to be sedated; however, it is better to anticipate the possibility by ensuring that they have nothing to eat or drink for several hours before the procedure and that they be accompanied by someone who can give consent for sedation.

Because of the more limited visual contact in the bore of the scanner, monitoring is more difficult with MRI than CT.⁵ When this is a substantial issue, an alternative to a sedated MRI examination, such as CT or involvement of an anesthesiologist or anesthetist, should be considered.

The pulse sequences in the MRI study must be priori-

tized for sedated and young children so that the initial pulse sequences and the selected planes provide the greatest amount of information. For the sedated child, the range of scanning opportunity is between 30 minutes and 1 hour.²² Beginning at about 1 hour, the infant or child is much more likely to wake up. This can happen very quickly as well. Occasionally, additional doses of sodium pentobarbital or fentanyl citrate (see earlier) can provide a longer period of sedation. Additional doses of chloral hydrate are not recommended. The sleepy child is at increased risk of aspiration of the oral sedative, and the length of time before the sedative takes effect is long and unpredictable.²²

For MRI, an initial amount at the top of the dose range of chloral hydrate (80 to 100 mg/kg) is recommended. Although additional amounts of IV sedative should be attempted if the maximum total dose has not been reached, this attempt may be unsuccessful and it is best to complete scanning within the suggested time.

If scanning time might exceed about 1.5 hours, use of an anesthetic agent should be considered. Usually an anesthesiologist or an intensive care specialist would be involved, requiring additional scheduling considerations.

Even when sedation is not required, young children have a limited ability to hold still. The length of the examination, the examination noises, and the enclosure (when the parent is not in visual contact) all contribute to this. For these children too, it is important to prioritize pulse sequences and planes. In addition to sedation, faster MRI sequences, such as fast spin echo, T2-weighting, and gradient sequences, and signal averaging³⁵ can help minimize the impact of random motion.

Blurring from bowel peristalsis can severely degrade abdominal MR images. Use of IV glucagon can reduce artifact, but it is unreliable, requires an injection, and is not routine for pediatric MRI. Negative-contrast MRI agents for the GI tract can improve the quality of abdominal images in children,⁶ but their use is not routine.

Several strategies can reduce artifact caused by periodic motion. Because most sequences in pediatric MRI are obtained during breathing, respiratory artifact is a concern,³¹ as it is for adults. Respiratory ordered-phase encoding is useful in older children, but it is less successful in infants and small children, in whom the transducer may not detect the smaller chest wall excursion. Fat suppression or saturation bands placed along chest or abdominal fat can be helpful, particularly in obese children. Respiratory artifact can be reduced with breath-holding, when possible, and with gradient imaging. Signal averaging can also reduce respiratory artifact, although at the expense of increased imaging time. When motion artifact is evident or anticipated, careful selection of a few sequences with more excitations (longer imaging time per sequence) may provide better quality than more sequences with less signal averaging.

The increased availability of a greater selection of coils during the 1990s resulted in excellent MRI quality across a wide range of pediatric ages. This includes specifically designed pediatric body and surface coils and adult coils modified for children. For example, excellent examinations of the torso can be obtained using a knee coil in a neonate and a head coil in an infant.^{3,7} As with any MRI study, the coil should be selected that provides the best signal-to-

noise ratio for spatial resolution, as well as penetration, while minimizing the sequence duration.³⁵

The use of IV contrast material that includes paramagnetic gadolinium chelate in MRI is similar to the use of iodinated material in CT. For single-dose applications, a dose of 0.1 to 0.2 mmol/kg is used.^{15, 27, 39} When dynamic scanning is indicated, such as in magnetic resonance angiography (MRA) or hepatic or renal imaging, a power injector can be used. Although injection protocols are not as developed for MRI as for CT, the rate of administration is generally lower with IV MRI contrast agents.²⁷ For nondynamic imaging, a hand bolus is usually sufficient. Bolus-tracking technology is also available on some MRI scanners,¹⁷ although it has not been applied in pediatric body MRI as commonly as in pediatric CT.

Contrast material for the GI tract is also available for pediatric scanning.⁴ Agents are classified as either positive (e.g., infant formula)²² or negative.⁶ Use of GI contrast agents in pediatric MRI is not routine.

Summary

The cross-sectional imaging modalities of CT and MRI are invaluable for pediatric imaging. The diagnostic potential of these modalities depends on obtaining optimal image quality. However, unique and often challenging technical demands can make scan optimization in children difficult. Nevertheless, excellent-quality images can be obtained in even the most complex circumstances when the radiologist applies strategies using appropriate scanning techniques.

Heart and Great Vessels

Sheila C. Berlin

The past two decades have seen major advances in pediatric cardiac imaging. Echocardiography has become the primary modality for imaging most forms of congenital heart disease. It provides high-resolution real-time images, the quality of which further improved with the introduction of new sonographic techniques such as tissue harmonics. Cardiologists have historically relied on the combination of echocardiography and cardiac catheterization for a comprehensive evaluation of patients with congenital heart disease. However, both modalities have important limitations; both are inconsistent in their ability to measure blood flow and quantify regional myocardial function. Echocardiographic access may be limited in older children, and the examination may be technically difficult in postoperative patients who have a wound or scarring. Cardiac catheterization is a costly, invasive examination, exposing children to radiation and complications. Furthermore, this two-dimensional (2D) technique sometimes necessitates difficult and inconclusive mental three-dimensional (3D) image reconstruction. Overcoming many of these limitations, magnetic resonance imaging (MRI) and helical computed tomography (CT) now offer excellent imaging alternatives in both infants and children with congenital heart disease.

During the 1990s, MRI emerged as an important, if not the premier, imaging modality in pediatric cardiac imaging. Since its introduction in the early 1980s,^{44, 73} cardiac MRI has evolved from a solid technique for anatomic description of the heart and great vessels and for information about nonquantifiable flow disturbances, to a study capable of providing accurate physiologic data and detailed 3D cardiovascular anatomy. In centers with state-of-the-art equipment, MRI serves an integral role in providing unique functional and morphologic information for a cost of only about 20% more than that of an echocardiogram.

MRI can now quantify volumes and masses of cardiac chambers, ejection fraction, stroke volumes, regurgitant volume and fraction, and regional biventricular myocardial function. This is particularly important for the right side of the heart, a focus of great concern in patients with congenital heart disease. Volumetric measurements of blood flow, which are difficult to obtain with other techniques, are potentially useful for quantitative evaluation of pulmonary artery flow, collateral flow, shunt lesions, valvular regurgitation, and ventricular filling.

Established applications for which MRI is well suited include evaluation of the aorta and its branches, pulmonary arteries, pulmonary venous connections, systemic veins, tetralogy of Fallot, heterotaxy syndrome, postoperative car-

diac baffles and conduits, pericardial and cardiac masses, and arrhythmogenic right ventricular dysplasia.

Helical CT generates similar high-quality images of the extracardiac vascularity in infants and children. Advantages of CT include the following:

1. Its relative ease of accessibility, particularly for critically ill patients traveling with life-support devices.
2. Its speed and the related limited sedation requirements.
3. Its increased spatial resolution relative to MRI.

Helical CT angiography allows the collection of volumetric data for 3D image reconstruction. It is an established technique for evaluation of aortic dissection and aneurysm^{63, 86} as well as for pulmonary embolism^{8, 39, 82} and vascular compression of the airway.^{49, 58} More recently, helical CT has proved a reliable means of evaluating branch pulmonary arteries, anomalous pulmonary veins, aortopulmonary collateral vessels, and postoperative shunts, conduits, and complicating thromboses.¹² Cine helical CT offers the added functional data for measuring chamber volume and for the direct calculation (without using geometric assumptions) of ejection fractions and cardiac output.

Techniques

Magnetic Resonance Imaging

Sedation

The average pediatric cardiovascular MRI examination takes 30 to 45 minutes. Because tolerance of this procedure varies widely among pediatric patients, anticipation of sedation requirements is essential.

Newborns can occasionally be scanned without sedation if feeding is withheld for 3 hours before the examination and then given immediately before scanning. Infants and young children can be safely and effectively sedated with intravenous (IV) sodium pentobarbital in an average total dose of 5 mg/kg. The drug is given in two parts, with the first delivered slowly over 30 seconds and additional medication given as needed. Scanning can usually be initiated within 10 minutes of delivery.

Older children with claustrophobia or anxiety can be sedated with 2 to 10 mg of (IV) diazepam. Resuscitation supplies and personnel trained in pediatric advanced life support must be available in the event of cardiorespiratory arrest.

In the case of significant cyanotic heart disease or other

risks for complication related to anesthesia, the patient should be sedated by a pediatric anesthesiologist.

Electrocardiographic Gating

Almost all pulse sequences designed for cardiovascular MRI require electrocardiographic (ECG) gating. To achieve high-quality images, the gating signal should be strong and free of artifact. Electrodes can be placed on the anterior or posterior chest. Anterior electrode placement generally returns a stronger signal, whereas posterior placement generates fewer artifacts.²⁷ Recent advances in gating technology promise quicker and easier methods.^{11, 20}

Pulse Sequences

Practical pediatric cardiovascular MR imaging requires appropriate selection among the many available pulse sequences and fine-tuning of individual sequence parameters. In general, anatomic imaging sequences fall into either one of two categories:

1. *Black-blood* sequences are most commonly used for anatomic description. They include conventional spin-echo (CSE) sequences and double or triple inversion recovery fast spin-echo (IRFSE) sequences.
2. *White-blood* sequences helpful in morphologic assessment include cine fast gradient-echo and gadolinium-enhanced 3D magnetic resonance angiography (3D MRA).

Four sequences are commonly used for collecting physiologic and functional information: (1) gradient-echo or general cine techniques, (2) myocardial tissue tagging, (3) blood or bolus tagging, and (4) phase-encoded velocity mapping.

Morphologic Assessment

Conventional Spin Echo. The standard initial anatomic evaluation begins with a non-breath-hold CSE sequence. This sequence is performed over an area of interest set up from the short, non-ECG-gated, fast gradient-recalled echo (GRE) localizers. With good ECG gating, high-resolution images with excellent signal-to-noise ratios (SNRs) are possible in most infants and children. The repetition time (TR) is set to the RR interval, and the echo time (TE) is approximately 20 msec; bandwidth is 16 kHz. Slice thickness varies from 2 to 7 mm with a minimum skip. Signal averages run from 2 to 5 with a matrix of 256 to 512 × 192. Limitations include a relatively long imaging time, sensitivity to motion artifact, and static-only images. Typically, a CSE is the first sequence run to define the morphology of vessel wall and airway or to characterize tissues such as in right ventricular dysplasia and cardiac masses.

Inversion Recovery Fast Spin Echo. The second black-blood sequence is the newer IRFSE designed for breath-hold imaging.⁹² Depending on the heart rate and sequence parameters, imaging times range from 10 to 20 seconds. A clear advantage over CSE is that IRFSE sequences generate quicker high-quality anatomic images in cooperative children. The TR is usually 2 RR intervals, TE about 40 msec, echo train length 32, and bandwidth 62.5

kHz. The slice thickness is 5 to 10 mm, and skip is usually minimal. The matrix is 256 × 152 to 256, and the number of signal averages is usually 1. Limitations include image acquisition only during the end-diastolic phase of the cardiac cycle, and reduced SNR compared to CSE images.

Gradient-Recalled Echo. The white-blood, fast gradient-echo sequence with segmented k-space filling is a very useful sequence that allows multiphase imaging in a short period of time. The sequence can be run with breath-holding using one signal average or without breath-holding using multiple averages. Imaging time for the former is approximately 2 to 5 minutes and for the latter, approximately 30 to 60 seconds per location. Images can be viewed in cine format at a workstation. Parameters include a minimum TR and TE, flip angle of 30 degrees, bandwidth of 32 Hz, slice thickness of 4 to 10 mm with minimal skip, matrix of 256 × 128, and four signal averages. Disadvantages of this sequence are reduced SNR and spatial resolution. As with all gradient-echo sequences, there is a greater sensitivity to susceptibility artifacts from metallic clips, stents, and wires.

Contrast-Enhanced 3D Magnetic Resonance Angiography. A newer white-blood sequence is the 3D fast spoiled gradient-echo sequence with IV administration of gadolinium-based contrast agent. A 3D data set that can be analyzed using postprocessing techniques, such as multiplanar reformatting and maximum intensity projection, is acquired. A 3D MRA sequence, which typically requires about 20 seconds per acquisition, is useful for demonstrating extracardiac vascular anatomy. In particular, the vessels of interest can be isolated from the full data set (Fig. 52-1) and displayed in multiple angiographic projections.

The circulation time of contrast medium varies with the size of the child, the injection site, intracardiac shunting, and the degree of impaired cardiac function. Timing of imaging relative to the contrast bolus can be determined using a test bolus technique^{41, 48} or an automated method such as SmartPrep.³⁴ Parameters include a minimum TR and TE (5/2), a flip angle of 25 to 45 degrees, a slice thickness of 2 mm, no gap, a 128 × 256 matrix, bandwidth of 62 kHz, and a single average of signal. A bolus dose of gadolinium (0.1 to 0.25 mmol/kg body weight) is followed by a 15-mL saline flush.

An injection rate of 0.3 to 0.8 mL/second is obtained with a power injector. An automated injector is recommended for small volumes of contrast material and short circulation times.⁴⁸ Limitations of 3D MRA are its inability to resolve intracardiac anatomy, dependence on breath-holding, and the need for satisfactory timing of image acquisition relative to contrast administration.

Physiologic and Functional Assessment

General Cine Gradient Echo. General cine GRE MRI, which is useful for both anatomic and functional assessment, has been discussed earlier. Acquisition of images at various phases in the cardiac cycle allows calculation of cardiac index, examination of wall motion, blood flow (e.g., shunts, stenoses, anastomoses), and valvular compe-

Figure 52-1. Possible aortic pseudocoarctation on echocardiography in an 8-year-old boy. *A*, Gadolinium-enhanced MR angiogram shows the classic anatomy of a right cervical aortic arch with a left descending aorta. *B*, Inversion recovery fast spin-echo (IRFSE) axial image shows posterior compression of the airway.

tence. A set of 16 frames is generally sufficient to evaluate the entire cardiac cycle. Images are usually obtained either parallel to the long axis of the heart (horizontal and vertical long-axis planes) or perpendicular to the long axis (short-axis planes).

Ventricular time-volume curves obtained with multislice cine GRE imaging can be used to assess systolic and diastolic function. In addition, static GRE images obtained at various levels (multislice, single phase) can “label” vessels with high signal intensity. This application is useful in detecting aortic collateral vessels in a patient with cyanotic heart disease.

GRE sequences readily identify turbulent flow (Fig. 52-2) as an area of signal void,⁸⁹ a property useful in detecting valvular or blood vessel stenosis and valvular regurgitation. The appearance of high-velocity flow and turbulence depends on technical factors, including display parameters (window width and level), flip angle, and TE. With long TE sequences (12 msec), the flow void is well demonstrated; with short TE sequences (<7 msec), it tends to disappear.

Myocardial Tissue Tagging. MRI is unique among imaging modalities in its ability to magnetically “tag” tissue. Tagging is achieved using a cine sequence in combination with a special sequence that destroys all the spins in a given plane, thus creating a line of signal void. The spatial modulation of magnetization (SPAMM) sequence^{1,2,112} is an example of such a technique. This sequence uses multiple radiofrequency pulses of 130 degrees, separated

in time, and a series of gradient radiofrequency pulses to produce saturated spins. Subsequently, a standard cine sequence divides the cardiac wall into cubes of magnetization.

Observing the translation, rotation, and deformation of the cubes allows assessment of wall motion, regional wall thickening, and strain. Tracking is performed in both 2D and 3D, in systole and diastole and as frequently as every 20 msec. Either manual or semiautomatic tracking of grid intersections on the image can be performed through the cardiac phases of interest.

Blood (Bolus) Tagging. The same concept that allows myocardial tissue tagging also allows tagging blood flow. Blood tagging is performed with a gradient-echo sequence that uses radiofrequency pulses to produce saturated spins along a line designated by the imager across a blood vessel. A saturation pulse precedes each acquisition.^{32,33} Blood flow then displaces this band of saturation while stationary structures keep the band’s original position. The displacement of the saturation band allows the calculation of velocity because the time between band placement and image acquisition is measurable.

Phase-Encoded Velocity Mapping. Velocity mapping in MRI is used for quantitative assessment of hemodynamics. The basic principle of the phase-encoding technique^{72,78} is that magnetic spins of intravascular protons flowing along a magnetic field gradient acquire a phase shift that is proportional to the flow velocity. Measuring phase from

Figure 52-2. Respiratory distress and tetralogy of Fallot with absent pulmonary valve in a 3-week-old infant. Single-phase image of a cine gradient-recalled echo (GRE) sequence through the long axis of the pulmonary outflow tract shows the turbulent flow across the rudimentary pulmonic valve.

signal amplitude allows calculation of velocity (Fig. 52-3), which can be done both parallel and perpendicular to the flow. Pressure gradients can be estimated from peak blood flow velocities (using the Bernoulli equation) in stenotic pulmonary arteries or surgical conduits.

Because flow volume can be measured, pulmonary artery flow, valvular regurgitation, left-to-right shunts, and ventricular filling can all be quantified. This technique provides accurate information on pulmonary flow volume and velocity after Fontan surgery⁷⁹ and on pulmonary regurgitation late after tetralogy of Fallot repair.⁷⁷

A limitation of this sequence is aliasing artifact, which occurs when the flow velocity in a vessel is underestimated. Velocities exceeding the expected range are displayed as flow in the opposite direction. Aliasing is easily corrected during postprocessing techniques.

Limitations

MRI can provide excellent images of both intracardiac and extracardiac anatomy. High-quality images, however, depend on a stable, cooperative patient who can breath-hold for at least several seconds. In addition, diagnostic images may be limited by difficult or impossible cardiac gating in patients with arrhythmia. Metallic clips and stents cause signal drop-off on MR images, which is more problematic than the beam-hardening artifact seen in CT. Signal loss is also caused by strong acceleration and turbulence, as at a site of severe stenosis.

The total setup and examination time for a cardiac MRI examination, even without sedation, is usually 30 to 45 minutes. Infants and small children usually require sedation for this duration. The cost at Rainbow Babies and Children's Hospital is about 20% more than for an echocardiogram and 30% more than for a contrast-enhanced 3D CT

scan. Although many cardiac lesions can be fully characterized by MRI or a combination of MRI and echocardiography, cardiac catheterization will be necessary in the foreseeable future to accurately measure pulmonary pressure and resistance in those being considered for the Fontan procedure. Finally, patients who have had pacemakers, pumps, or stent placement for less than 6 weeks are not candidates for MRI.

Computed Tomography

Sedation

Most infants and children do not require sedation for helical cardiac CT imaging. Total scanning time usually does not exceed 20 seconds, a duration short enough for most patients to tolerate gentle wrapping, restraint, and coaching. Light sedation, typically with choral hydrate, can be given to older infants and small, uncooperative children.

Electrocardiographic Gating

Newer, multirow, multidetector scanners offer both prospective and retrospective cardiac gating. A robust ECG signal allows gating as effective as that obtained with MRI.

Imaging Parameters

Delivery of Contrast Material

In most children, 2 mL of nonionic iodinated contrast material per kilogram of body weight can be administered by a power injector into the largest available extremity vein. An angiocatheter of 22 gauge or larger is recommended.

For the newborn or small infant, increasing the contrast

Figure 52-3. Magnitude (A) and phase (B) images of the phase-encoded velocity-mapping technique. Images are obtained perpendicular to flow to map the velocity in the descending aorta. Graphic display (C) of maximum velocity through a single cardiac cycle.

dose to 2.5 to 3 mL/kg and delivering the dose by hand are acceptable. Scanning can be started approximately 15 seconds after initiation of the bolus. This should allow time for opacification of all chambers and great vessels. When hand-injection is used, scanning should begin after approximately 60% of the contrast medium has been delivered. This scanning delay period is shorter than that used in adults because of the shorter circulation time and higher heart rate in infants.

An injection rate of 2.5 to 3.0 mL/second is appropriate with adequate IV access. The bolus is followed with a 10-mL bolus of saline to minimize the venous inflow streak artifact and to maximize the dose of contrast material, particularly when the allowable dose is small.

Scan Technique

An initial scout image of the chest and upper abdomen maps the longitudinal field of view of the helical scan. The transverse field of view can be adapted to the patient's body

size. Selection of collimation and table motion depends on the likelihood of motion artifact from respiration or lack of cooperation.

In breath-holding or quietly breathing older children, narrow collimation (1.5 mm) and a pitch of 0.875 to 1.0 can be used. In the rapidly breathing, uncooperative patient, collimation can be widened to 3 mm and the pitch increased to 2.0. Scanning of the heart and great vessels proceeds in an inferior-to-superior direction for an upper extremity vein injection and the reverse for a lower extremity injection. Scanning parameters of 90 to 120 (kVp) and 125 to 260 mAs are appropriate for most pediatric patients. Postprocessing techniques include both maximum intensity projection and multiplanar reformatting for display of 3D images.

Limitations

Helical CT exposes children to ionizing radiation and the small risk of an adverse reaction to contrast material.

This technique is also sensitive to miscalculation of the peak opacification of the cardiac chambers and great vessels. If the contrast bolus arrives either too early or too late with respect to scanning time, images may not be diagnostic. If an unsedated child moves during the scan, the bolus will be lost and cannot be readministered immediately because of recommended contrast limits. CT images are degraded by beam-hardening artifact of metallic wires, clips, and coils, although the effect here is not as great as the susceptibility artifact in MRI.

Applications

Aortic Arch Anomalies

Anomalies of the aorta, such as coarctation, supraaortic stenosis, interrupted aortic arch, cervical aortic arch, double aortic arch, and aberrant subclavian artery, can be accurately diagnosed with MRI.^{37, 102}

Coarctation

Coarctation of the aorta is the most common symptomatic congenital lesion of the aortic arch. The focal narrowing present in the proximal thoracic aorta, typically in the juxtaductal region, is classified as either "focal" or "diffuse." A bicuspid valve is reported in 75% to 85% of cases, and there is an association with other congenital lesions of the left side of the heart, including tubular hypoplasia of the arch.⁶

Accurate assessment of the site and severity of the aortic lesion, as well as any involvement of the brachiocephalic vessels, is important for preoperative planning. For evaluation of coarctation of the aorta, IRFSE black-blood imaging in the axial and steep left antero-oblique planes clearly delineate the anatomy (Fig. 52-4) in most patients.

In infants and very small children, more time-consuming CSE images with multiple averages may be necessary to define the anatomy. Cine GRE shows turbulent flow at and beyond the site of coarctation (Fig. 52-5), or within, above, or below the aortic valve. Gadolinium-enhanced MRA best displays the 3D anatomy of the aorta and brachiocephalic vessels. Phase-contrast images acquired just beyond the coarctation site determine the maximum velocity and allow for calculation of a pressure gradient.⁹⁸

Other Anomalies

Thoracic arch anomalies are common, occurring in 0.5% to 3% of the population. These arch anomalies may be associated with congenital heart disease, may form a vascular ring, or may be isolated findings and asymptomatic. A double aortic arch, present in about 0.3% of autopsies, is the most common vascular ring as well as the most common ring to be symptomatic.²⁹ The right arch is generally higher in position and larger in size than the left arch, and it passes posterior to the trachea and esophagus to join the descending aorta that is characteristically left-sided. Less frequently, however, the left arch can be the same size as or larger than the right arch. Alternatively, a portion of the smaller arch may exist only as a fibrous cord. In cases of partial left arch atresia, the descending aorta is typically right-sided.

Arch variants, such as double aortic arch and right arch with aberrant left subclavian artery, are well visualized

Figure 52-4. Pressure gradient measured by echocardiography after repair of a focal aortic coarctation in a 10-year-old boy. Cross-sectional echocardiographic image in the left anterior oblique plane shows a residual narrowing at the coarctation site.

Figure 52-5. Single phase of a cine gradient-recalled echo sequence, left anterior oblique projection, shows a poststenotic jet just beyond the coarctation site.

Figure 52-6. Stridor in a 2-month-old infant. A double aortic arch is seen in the 3D CT angiogram.

with either MRI^{53, 67} or CT.^{49, 58} Although the black-blood technique IRFSE is usually adequate, smaller patients may require CSE images acquired with multiple signal averages to achieve a high-enough SNR. The diagnosis is generally obvious on the individual axial images of helical CT, but 3D reconstruction (Fig. 52-6) is a simpler means of projecting the global anatomy (including the airway) to referring clinicians and surgeons.

Pulmonary Arteries

The pulmonary arteries are commonly involved in congenital heart lesions, particularly in cases of right ventricular outflow tract obstruction. Identification and precise description of the pulmonary arteries is critical in treatment planning and assessing patient risk.⁷⁴

Pulmonary artery confluence/nonconfluence, stenoses, and the presence of aorticopulmonary collaterals can alter the approach to medical and surgical management. Measurement of pulmonary artery size on angiocardiology, the longtime reference standard, is inaccurate because of magnification. Also, angiocardiology may fail to demonstrate central pulmonary arteries identified at surgery or autopsy.⁹⁶ In some cases, it is impossible to accurately delineate the pulmonary artery anatomy in one angiographic study because of contrast volume limits. Echocardiography may be unsuccessful in demonstrating the morphology of the distal main pulmonary arteries (particularly the left³⁸), largely because of interposition of lung tissue.

MRI has shown promising results in evaluation of presence, size, and distribution of central pulmonary arteries.^{16, 38, 42, 46, 80, 99, 105} Coronal and oblique-coronal CSE images, obtained parallel to the long axis of the vessel, provide

accurate visualization up to the first or second hilar branch.⁴² Other factors contributing to treatment planning, such as the status of the pulmonary artery confluence and the presence of aorticopulmonary collaterals, are also reliably evaluated with MRI.

More recently, both electron beam and volumetric helical CT angiography have shown high-quality pulmonary artery anatomy.^{108, 109} In a 1999 study,¹⁰⁸ helical CT angiography with 3D reconstruction was superior to echocardiography for the noninvasive assessment of pulmonary artery anatomy in patients with complex congenital heart disease. Helical CT was as accurate as angiocardiology in revealing stenotic or nonconfluent central pulmonary arteries and aorticopulmonary collaterals.

Aberrant origin of the left pulmonary artery (pulmonary sling) can be clearly imaged with either MRI (Fig. 52-7) or helical CT (Fig. 52-8). Associated airway anomalies such as tracheal rings or bronchus suis (Fig. 52-9) are also demonstrated with either MR CSE sequences or 3D reconstruction of the airway on helical CT. Absent pulmonary valve is another lesion well evaluated by MRI. CSE MR images clearly define the dilated pulmonary arteries (Fig. 52-10) and their relationship to the airway, whereas cine GRE images display flow disturbances typical at the pulmonary valve region. Phase-contrast images can measure regurgitant volume into the right ventricle.

Pulmonary Venous Connections

Echocardiographic evaluation of the pulmonary veins is limited because of poor far-field resolution, overlying lung and bronchi, and a generally small field of view. Without accurate echocardiographic information, poor levophase images of the pulmonary veins and selective pulmonary venograms may result in misdiagnosis of pulmonary venous connections at angiocardiology. MRI can depict pulmonary venous connection anomalies such as partial and total anomalous connections and cor triatriatum.^{21, 71, 104} In a large study evaluating 56 patients with congenital heart disease with normal pulmonary venous connection and 22 patients with anomalous pulmonary venous return, the venous connections were correctly identified on axial MR images in 88% and 95% of patients, respectively.⁷¹ In a small number of surgically proven cases, the accuracy of MRI in the diagnosis of total anomalous pulmonary venous connections was 100%, better than that of angiocardiology (25%) or echocardiography (57%).²¹

The typical findings of total anomalous pulmonary venous connection on MR images include (1) a venous structure posterior to the left atrium, (2) a small left atrium and ventricle, (3) an atrial septal defect (in most cases), and (4) a vertical vein (in some cases).²¹ Axial CSE and gadolinium-enhanced MRA are the preferred modalities for showing the anatomy (Fig. 52-11).

Heterotaxy Syndrome

MRI is well suited for the "segmental analysis"¹⁰² of heterotaxy syndrome. The segmental approach requires documentation of the following anatomy: (1) positions of

Figure 52-7. Respiratory distress in a 1-month-old infant. Coronal (A) and axial (B) cross-sectional echocardiographic images show the aberrant origin of the left pulmonary artery from the right. Airway narrowing is also noted.

Figure 52-8. Failure to thrive and respiratory distress in a 2-month-old infant. Axial CT image shows the left pulmonary artery as it courses behind the trachea and anterior to the esophagus.

Figure 52-9. Respiratory distress in a 1-month-old infant. Coronal cross-sectional echocardiographic image through the trachea shows a bronchus suis.

Figure 52-10. Tetralogy of Fallot and absent pulmonary valve in a 2-week-old infant. Coronal cross-sectional echocardiographic image shows aneurysmal dilatation of the pulmonary arteries and uplifting of the right main bronchus.

the atria, main bronchi, and ventricles; (2) atrioventricular relationships; (3) great vessel morphology; and (4) other intracardiac and extracardiac anomalies, such as polysplenia and a midline liver. In a 1994 prospective study, the value of MRI in preoperative planning for the heterotaxy syndrome was compared with that of echocardiography and cardiac catheterization.³⁶ MRI provided excellent anatomic and functional information not available from either echocardiography or cardiac catheterization in some patients.

In most cases of viscerotransposition abnormalities, the situs of the atria can be determined by the MR appearance of the appendages. The morphologic right atrial appendage has a broad junction with the atrial chamber and a promi-

nent terminal crest and pectinate muscles. The morphologic left atrial appendage has a narrow junction with the atrial chamber and no terminal crest. Bronchial situs is best seen on coronal images in plane with the carina.

Postoperative Cardiac Baffles and Conduits

Visualization of intracardiac and extracardiac conduits by echocardiography and angiocardiology has been inconsistent. Limited echocardiographic access usually prohibits visualization of the full course of a conduit. Maximum contrast dosage and prolonged radiation may influence the number of angiographic runs performed, thereby limiting visualization of conduits.

MRI visualizes the anatomy of extracardiac conduits in their entirety more often than angiocardiology or echocardiography.^{12, 60} MRI has an unlimited number of viewing planes, thus avoiding the overlap of structures seen with angiocardiology. Furthermore, 3D MRA images can be rotated 360 degrees and defines the spatial interrelations of vascular and nonvascular structures.

Baffles, shunts, and conduits can be delineated by IR-FSE or CSE images (Fig. 52-12), GRE (Fig. 52-13) or MRA techniques. The anatomy of the Rastelli and Jantene procedures is depicted on axial and sagittal images. The results of the Senning and Damus procedures are best visualized in the sagittal or coronal planes. The modified Blalock-Taussig shunt is best depicted on sagittal or coronal images (Fig. 52-14) and cavopulmonary shunts on oblique-coronal images.

Pericardial and Cardiac Masses

As image acquisition with CT and MRI has become faster, these modalities have played an increasingly important role in the evaluation of cardiac neoplasms.^{3, 23, 66, 69, 90, 113} Although spatial and temporal resolution is lower than with echocardiography, the soft tissue contrast of

Figure 52-11. Marfan syndrome in an 8-month-old infant. Cross-sectional echocardiographic axial image shows both the dilated aortic root and the absent left pulmonary veins.

Figure 52-12. Central shunt in a 2-month-old infant with pulmonary atresia. Axial cross-sectional echocardiographic image shows flow void in the patent central shunt (S), which courses from the anterior ascending aorta to the pulmonary artery.

both CT and MRI is superior to that of echocardiography. Furthermore, both modalities allow imaging of the entire mediastinum and evaluation of the extracardiac extent of disease. CT can detect calcification, an important variable in the differential diagnosis of cardiac neoplasms. In addition, CT is faster and easier to perform, and it generally produces more reliable image quality. MRI has better soft tissue contrast than CT and offers greater flexibility in selection of imaging planes.

MRI examination for a cardiac mass should include a CSE sequence for anatomy, supplemented by a cine GRE sequence to assess for flow disturbance at the valve level or effect on myocardial contractility. Fat-saturated sequences are helpful in the diagnosis of a lipoma. Gadolinium is helpful in distinguishing between thrombus and soft tissue mass (Fig. 52-15) because thrombus does not enhance.

Teratomas and pericardial cysts are the most common pericardial lesions in children. Cardiac masses seen in the pediatric population include myxoma (7% occur in setting of Carney complex), fibroma, lymphangioma, lipoma, and rhabdomyoma.

Myxomas associated with the Carney complex are more likely to occur outside the left atrium, to be multifocal, and to recur after resection.^{17, 76, 83} Because of their gelatinous nature, myxomas usually show heterogeneous low attenuation on CT scans. Calcification is a frequent finding on CT. Prolapse across cardiac valves may be seen with CT or MRI. Markedly increased signal intensity on T2-weighted images is typical of a myxoma, although scattered foci of decreased signal from calcification or hemosiderin may be present.

Cardiac fibroma is the second most common benign primary cardiac tumor in children after rhabdomyoma.¹⁵ Most cases are detected in infants or in utero.^{7, 15} The prevalence of cardiac fibroma is increased in Gorlin's syndrome.¹⁵ This tumor arises in the myocardial wall, almost always in the ventricles. It is large, with a mean diameter of about 5 cm,¹⁵ often obliterating the ventricular cavity (Fig. 52-16). On CT studies, fibromas typically show uniform soft tissue attenuation, often with calcification. The dense, fibrous tissue of these tumors shows hypointensity on T2-weighted images and isointensity relative to muscle on T1-weighted images. Little or no enhancement with gadolinium is the most common presentation;¹⁰⁷ however, the enhancement pattern is truly variable with both homogeneous and heterogeneous patterns of enhancement reported.¹⁴

Figure 52-13. After a Mustard procedure for transposition of the great arteries in a 14-year-old patient, cine gradient-recalled echo (GRE) was performed to determine whether there was a baffle obstruction. A single phase from the GRE sequence shows patent baffle flow without turbulence.

Figure 52-14. Postoperative right modified Blalock-Taussig (BT) shunt with pericardial roll to the left pulmonary artery in a 3-month-old girl. *A*, Cross-sectional echocardiographic (CSE) sagittal image shows patency of the BT shunt to the large pericardial roll. *B*, CSE coronal image shows patency of the roll and left pulmonary artery anastomosis. *C*, Also noted is marked left main bronchus compression between the roll and left pulmonary artery.

Figure 52-15. Tricuspid atresia and right atrial mass after a Fontan procedure in a 13-year-old girl. *A*, Unenhanced cross-sectional echocardiographic axial image shows a bright signal thrombus surrounded by slow flow. *B*, Coronal gradient-recalled echocardiographic image shows flow around the thrombus.

In infants, the primary differential diagnosis of an intramural mass is a cardiac rhabdomyoma, accounting for more than 50% of pediatric intracardiac masses. If there are multiple masses or other signs of tuberous sclerosis, rhabdomyoma can be diagnosed with confidence.⁷ If the tumor is solitary, ventricular, and calcified, the diagnosis of fibroma is confirmed.

Rhabdomyosarcoma, a rare malignant tumor, occurs much less commonly in children than in adults. It occurs with equal frequency in all cardiac chambers and does not calcify.⁴ Often cystic or necrotic, it may invade pulmonary veins, the pericardial space, or other adjacent structures.⁴

Summary

Extraordinary technical advances over the past decade have paved the way for less invasive diagnostic tests in cardiac imaging such as MRI and CT. These studies not only render the same diagnostic information as cardiac catheterization but also offer more accurate quantitative information, such as about the volume and mass of cardiac chambers. We are currently on the threshold of a revolutionary change in the way we diagnose and treat cardiovascular disease. The current limitations in temporal resolution will be soon be overcome by "real-time" sequences.^{59, 81, 103, 111}

Figure 52-16. Cardiac fibroma in a 5-week-old infant who has had a murmur since birth. Sagittal cross-sectional echocardiographic unenhanced T1-weighted (*A*) and T2-weighted (*B*) images show a large, well-circumscribed soft tissue mass arising from the free wall of the right ventricle. Intermediate signal of the mass is noted on both sequences.

MRI-guided interventional cardiology⁶⁵ is in the earliest stages of development, but it is a promising new approach just on the horizon.

One of the major barriers to widespread utilization of cardiac CT or MRI is the question of who should perform and interpret these studies—radiologists or cardiologists. Few radiologists are experts in pediatric cardiac disease, and few cardiologists are experts in CT and MRI. Therefore, the current solution will involve an interdisciplinary effort to fully realize the possibilities of this remarkable revolution.

Chest

Lane F. Donnelly

There are many similarities and differences in the use of cross-sectional imaging methods—computed tomography (CT) and magnetic resonance imaging (MRI)—for imaging the chest of a child compared with that of an adult. In many clinical scenarios, such as the evaluation of pulmonary metastatic disease (one of the more common indications for CT scanning of the chest), there are more similarities than differences. This chapter focuses on the clinical issues for which there are significant differences in the uses of cross-sectional imaging of the chest in children and in adults and serves as a complement to other chapters covering issues concerning CT and MRI of the chest in adults.

The chapter discusses the lung, mediastinum, and chest wall. Concerning CT and MRI, CT has a more dominant role in the imaging of most diseases of the pediatric chest and is emphasized here. Several of the areas in which MRI is used with more frequency, such as cardiac imaging and evaluation of vascular rings, are covered in Chapter 52 and are not repeated. For areas in which MRI is advantageous, compared with CT, the emphasis is on MRI. In addition, adaptation of techniques and protocols for CT and MRI in pediatric imaging is discussed in Chapter 52 and is not repeated here.

Special Considerations in the Pediatric Lung

There are several scenarios in which either the disease processes that are present or the use of CT in the evaluation of these diseases differs in children. These scenarios include (1) the use of CT in the evaluation of pediatric lung masses, (2) suppurative complications of pneumonia, (3) the immunocompromised child with potential pneumonia, (4) pulmonary trauma, and (5) cystic fibrosis.

Focal Pediatric Lung Masses or Lesions

Issues pertaining to the evaluation of metastatic lung lesions are similar in children and in adults. In contrast to the situation with adults, in whom a large percentage of lung masses represent bronchogenic carcinoma, primary lung neoplasms, such as pulmonary blastoma, are exceedingly rare in children. More commonly, focal lung masses in children are related to congenital lung lesions, including such entities as congenital cystic adenomatoid malformation (CCAM), sequestration, bronchogenic cyst, and congenital lobar emphysema. Such masses can present during childhood or, less commonly, adulthood; most often, these lesions present during early childhood.

When a suspected congenital lung lesion is encountered

on radiographs of the chest, CT scans are usually obtained to further characterize the lesion and to define its extent. These lesions may present as respiratory distress in the newborn or as recurrent pneumonia. Some are identified in utero with sonography.

When encountered in the neonatal period, the differential for a focal lung lesion can be separated on the basis of whether the lesion appears lucent or solid on the chest radiograph.⁹ Most likely considerations for a lucent chest lesion in a newborn include congenital lobar emphysema, CCAM, persistent pulmonary interstitial emphysema, and congenital diaphragmatic hernia. CT may be helpful in differentiating these lesions by demonstrating whether the abnormal lucency is related to air in distended alveoli or the interstitium or within abnormal cystic structures⁹ (Figs. 53-1 to 53-4). Lesions that typically appear solid and nonlucent during the neonatal period include sequestration and bronchogenic cysts.

Congenital Cystic Adenomatoid Malformation

CCAM is a congenital adenomatoid proliferation that replaces normal alveoli. The majority involve only one lobe, and unlike congenital lobar emphysema, there is no lobar predilection. CCAMs are divided into three types on the basis of how large the cysts appear on imaging or at pathology^{26, 35}:

Type 1 lesions (50%) have one or more large (2- to 10-cm) cysts (see Fig. 53-1).

Figure 53-1. Type 1 congenital cystic adenomatoid malformation in a 16-month-old boy. CT scan shows large air-filled cyst (C) occupying most the right hemithorax. The right lower lobe is compressed (arrow), and there is leftward mediastinal shift.

Figure 53-2. Type 2 congenital cystic adenomatoid malformation in a 2-day-old boy. CT scan shows abnormal density and lucency within the right lower lobe (arrows). The diameters of the small air-filled cystic structures within the mass are smaller than the spaces between normal interstitial markings, differentiating this congenital cystic adenomatoid malformation from congenital lobar emphysema.

Type 2 lesions (40%) have numerous small cysts of uniform size (see Fig. 53-2).

Type 3 lesions (10%) appear solid on gross inspection and imaging but have microscopic cysts.

The classification system has no clinical relevance except that it is a reminder that CCAMs can have multiple imaging appearances.

The imaging appearance reflects the type. CCAMs communicate with the bronchial tree at birth and therefore fill with air within the first hours to days of life^{9, 26, 35} (see Figs. 53-1 and 53-2). On radiography and CT, a com-

Figure 53-3. Congenital lobar emphysema in a 23-month-old girl. CT scan shows asymmetrical low attenuation within the left upper lobe. The pulmonary vessels are attenuated compared with those on the right, and the spaces between the vessels are greater on the left than those on the right.

Figure 53-4. Persistent pulmonary interstitial emphysema in a 9-day-old girl. CT scan shows areas of lucency with central nodular and linear opacities (interstitial vascular structures) (arrows), documenting that the abnormal gas collection is within the interstitial space. (From Donnelly LF, Frush DP: Localized lucent chest lesions in neonates: Causes and differentiation. *AJR Am J Roentgenol* 172:1651, 1999.)

pletely cystic mass, mixed cystic and solid mass, or solid mass is seen, depending on the number and size of cysts and on whether those cysts contain air or fluid.^{9, 26, 35} The management of symptomatic CCAMs consists of surgical resection. The management of asymptomatic CCAMs is somewhat controversial, but most advocate elective resection because these lesions are at an increased risk of infection and, although rare, rhabdomyosarcoma can develop.

An increasingly encountered scenario is a prenatally diagnosed lung mass that becomes less prominent on serial prenatal ultrasounds and demonstrates only subtle findings or is not detected on a chest radiograph obtained soon after birth.⁴² Almost all such lesions are type 2 CCAMs and demonstrate abnormalities on CT even when chest radiographic findings are normal.⁴²

Congenital Lobar Emphysema

Congenital lobar emphysema is related to overexpansion of the alveoli. The cause is debated. There can be associated anomalies, usually cardiac, but this occurs in the minority of patients. There is a lobar predilection, with the most common site being the left upper lobe (43%), followed by the right middle lobe (32%) and right lower lobe (20%).³⁸

On chest radiography, a hyperlucent, hyperexpanded lobe is seen. On initial radiographs, the lesion may appear of soft tissue density related to retained fetal lung fluid. This density resolves and is replaced by progressive hyperlucency.⁹

On CT, air is in the alveoli, and the interstitial septa and bronchovascular bundles are thus at the periphery (not the center) of the lucency. The air spaces are larger than the adjacent normal lung, and pulmonary vessels appear attenuated^{9, 38} (see Fig. 53-3). The treatment is lobectomy.

Persistent Pulmonary Interstitial Emphysema

Most commonly, pulmonary interstitial emphysema is a transient phenomenon related to air leak in premature neonates as a result of barotrauma. Its significance lies in that it is a warning sign of another potential air-block complication, such as pneumothorax or pneumomediastinum. Occasionally, pulmonary interstitial emphysema can persist and develop into an expansive, multicystic mass.^{9,24} The air cysts can become sufficiently large to cause mediastinal shift and compromise pulmonary function.

The primary therapy for persistent pulmonary interstitial emphysema is nonsurgical, including selective intubation of the opposite lung or decubitus positioning. Therefore, differentiation from other air-filled cystic masses that are treated surgically, such as CCAMs, is important. On CT scans, the air cysts are in the interstitial space, with the bronchovascular bundles positioned within the center of the air cysts.^{9,24} They appear as linear or nodular densities in the center of the cysts^{9,24} (see Fig. 53-4).

Sequestration

Pulmonary sequestration refers to a congenital area of abnormal pulmonary tissue that does not have a normal connection to the bronchial tree. The characteristic feature of sequestration is the demonstration of anomalous arterial supply to the abnormal lung via a systemic artery that arises from the aorta. All modalities that can demonstrate this abnormal systemic arterial supply, including MRI, helical CT, sonography, and arteriography, have been advocated in making the diagnosis of sequestration. Helical CT is the imaging modality of choice because it both visualizes the systemic arterial supply when a sequestration is present and further characterizes the lung abnormality if a sequestration is not present.²²

On CT scans, the sequestration appears as soft tissue attenuation with the affected lung. The systemic arterial feeder is identified as an enhancing vessel that arises from the descending aorta and extends to the sequestration²² (Fig. 53-5). The systemic arterial arteries can vary in size, from several millimeters in diameter to very large arterial structures. Because sequestrations do not communicate with the bronchial tree unless they become infected, in the neonatal period sequestrations appear as a radiopaque mass.⁹ After infection has occurred, air may be introduced and sequestrations may appear as multiloculated cystic masses.²² The most common location is within the left lower lobe.

Much debate has focused on differentiation of *intralobar* and *extralobar* sequestrations. Extralobar sequestrations are characterized by a separate pleural covering; intralobar sequestrations, which are more common, are not. Extralobar sequestrations are associated with other abnormalities in 65% of cases; intralobar sequestrations are not. Differences in venous drainage patterns have been emphasized, but they vary with both types. The differentiation between intralobar and extralobar sequestration cannot be made at imaging and does not affect surgical management.²² Visualization of the supplying systemic artery is the characteristic finding and the documentation that the surgeons are looking for before surgical removal of the lesion.

Figure 53-5. Sequestration in a 1-day-old boy. CT scan shows abnormal opacity (S) within the left lower lobe. An enhancing systemic artery (arrow) is seen arising from the aorta and leading into the lung opacity.

Bronchogenic Cysts

Bronchogenic cysts occur secondary to abnormal budding of the tracheobronchial tree during development and occur in the lung parenchyma and mediastinum with equal frequency.²³ Like sequestrations, they do not contain air until they become infected and thus may appear as well-defined soft tissue attenuation or cystic air-fluid-containing masses.²³ They can be quite large. They appear as well-defined cystic structures on images (Fig. 53-6). When they

Figure 53-6. Bronchogenic cyst in a 10-month-old boy. CT scan shows well-defined, nonenhancing mass (B) within the right parahilar region.

occur within the lung, the most common location for a bronchogenic cyst is central within the perihilar areas.

Imaging of Suppurative Complications of Pneumonia

Respiratory tract infection is the most common cause of illness in children and continues to be a significant cause of complications and death.⁴ Because of its frequency, an understanding of the appropriate roles of imaging in these children is important.

The roles of imaging in the evaluation of immunocompetent children with community-acquired pneumonia are multiple: (1) confirmation or exclusion of pneumonia, (2) characterization and prediction of the infectious agent, (3) exclusion of other causes of the symptoms, (4) evaluation when there is failure to resolve, and (5) evaluation of related complications.⁶ Radiography of the chest remains the primary imaging modality in most of these scenarios, and CT plays a secondary role in most of these respects.

Concerning the confirmation or exclusion of pneumonia, CT usually plays no role in making the diagnosis of pneumonia and, consequently, in treatment determination and patient disposition. This is accomplished with radiography of the chest.⁶ Also, characterization of a lower respiratory tract infection as probably viral or bacterial pneumonia is accomplished through a combination of clinical examination and radiography of the chest.⁶ CT plays no role.

CT sometimes has a role in the child who has pneumonia that is recurrent or fails to resolve. Unlike the case with adults, in whom postobstructive pneumonia secondary to bronchogenic carcinoma is a concern, follow-up radiography to ensure resolution of radiographic findings is not routinely necessary in an otherwise healthy child who has had pneumonia. Causes of failure of suspected pneumonia to resolve include infected developmental lesions (as discussed previously), bronchial obstruction, gastroesophageal reflux and aspiration, and underlying systemic disorders.

Complications

The evaluation of complications related to community-acquired pneumonia can be divided into two clinical scenarios: (1) primary evaluation of parapneumonic effusions and (2) evaluation of the child who has persistent or progressive symptoms despite medical or surgical therapy.

Primary Evaluation of Parapneumonic Effusions

Parapneumonic effusions occur commonly in patients with bacterial pneumonia. There are differences in opinion between many pediatric surgeons and pediatric pulmonologists regarding the timing and aggressiveness of the management of parapneumonic effusions. Many investigators advocate the use of antibiotics, drainage tube placement, and thrombolytic therapy.⁶ Other investigators advocate early intervention with thoracoscopy and débridement.⁶ The indications for imaging these effusions reflect the patterns of management at specific institutions. Traditionally, the aggressiveness of therapy has been based on categorization of parapneumonic effusions as *empyema* or *transudative effusion* on the basis of aspiration and analysis of pleural

fluid.²⁷ Multiple attempts have been made to use imaging criteria to differentiate empyema from transudative effusion so that every child with a parapneumonic effusion does not have to undergo diagnostic thoracentesis.

In the past, CT was advocated in the differentiation between empyema and transudative parapneumonic effusion.^{31, 39} CT findings of enhancement and thickening of the parietal and visceral pleura, thickening of the extrapleural subcostal tissues, and increased attenuation of the extrapleural subcostal fat were described as highly accurate in differentiating empyema from transudate^{31, 39} and should be used to influence therapeutic decisions in the management of parapneumonic effusions. Later studies, however, have shown these findings to be inaccurate in determining which parapneumonic effusions meet the laboratory criteria for empyema in children and that the presence or absence of such CT findings should not influence therapeutic decisions concerning the management of parapneumonic effusions.¹⁴

A study³⁴ advocated the use of sonography to aid in making therapeutic decisions regarding parapneumonic effusions. In this study, parapneumonic effusions were categorized as low grade (anechoic fluid without internal heterogeneous echogenic structures) or high grade (fibrinopurulent organization demonstrated by the presence of fronds, septations, or loculations). In children with high-grade effusions, length of hospitalization was reduced by nearly 50% when surgical intervention was performed.³⁴ Length of hospitalization in children with low-grade effusions was not affected by surgical intervention.³⁴ Therefore, sonography may play a more useful role than CT in the early evaluation of parapneumonic effusions.

Evaluation of Persistent or Progressive Symptoms

When children exhibit persistent or progressive symptoms (e.g., fever, respiratory distress, sepsis) despite appropriate medical management of pneumonia, there often is an underlying suppurative complication.¹³ Potential suppurative complications include parapneumonic effusions such as empyema, other inadequately drained effusions, and malpositioned chest tubes. Parenchymal complications (e.g., cavitary necrosis, lung abscess) and purulent pericarditis are also possibilities.^{6, 13}

Although chest radiography is the primary imaging modality for detecting such complications, a significant percentage of these complications are not demonstrated on radiography.^{6, 13} Contrast-enhanced CT is useful in detecting clinically significant suppurative complications.^{6, 12, 13, 15} CT can help to differentiate whether the persistent illness is pleural or related to lung parenchyma, directing therapy in the appropriate direction.¹³ The intravenous administration of contrast medium is vital in maximizing the detection and characterization of both lung parenchymal and pleural complications.^{12, 13, 15} This is one of the few indications for the use of intravenous contrast medium when chest CT is performed primarily to image lung disease.

Lung Parenchymal Complications

On contrast-enhanced CT, noncompromised lung parenchyma consolidated with pneumonia enhances diffusely.¹⁵ This enhancement is not surprising, given the degree of

inflammation associated with pneumonia. Large areas of decreased or absent enhancement are indicative of underlying parenchymal ischemia or impending infarction.¹⁵ In one study,¹⁵ the presence of decreased enhancement was associated with a significantly increased rate of admission to the intensive care unit, increased length of hospitalization, and increased incidence of the development of cavitory necrosis. Therefore, the detection of the presence of decreased lung enhancement in this setting yields important prognostic information.

Suppurative lung parenchymal complications represent a spectrum of abnormalities, including cavitory necrosis, lung abscess, pneumatocele, bronchopleural fistula, and pulmonary gangrene.¹⁵ The name given to the suppurative process depends on several factors, including the severity and distribution of the process, the condition of the adjacent lung parenchyma, and the temporal relationship with disease resolution.^{15, 32}

Lung abscess represents a dominant focus of suppuration surrounded by a well-formed fibrous wall.^{15, 32} On contrast-enhanced CT scans, lung abscesses appear as fluid-filled or air-filled cavities with definable, enhancing walls.^{15, 32} Typically, there is no evidence of necrosis in the surrounding lung. *Pneumatocele* is a term given to thin-walled cysts seen on imaging and may represent a later or less severe stage of resolving or healing necrosis⁶ (Fig. 53-7). On CT scans, a thin-walled cyst containing air with or without fluid is identified. The wall does not enhance. The surrounding lung may be opacified but does not demonstrate findings of necrosis. Bronchopleural fistulas are identified on CT when a direct communication is visualized between the air spaces of the lung and the pleural space.^{6, 13}

Cavitory necrosis represents a dominant area of necrosis of a consolidated lobe associated with a varying number of thin-walled cysts.^{12, 15} The mechanism of necrosis complicating pneumonia is related to thrombotic occlusion of alveolar capillaries associated with adjacent inflammation, resulting in ischemia and eventually necrosis of the lung

parenchyma. The characteristic CT findings of cavitory necrosis include loss of normal lung architecture, decreased parenchymal enhancement, loss of the lung-pleural margin, and multiple thin-walled cavities that contain air or fluid and lack an enhancing border^{12, 15} (Fig. 53-8).

Historically, cavitory necrosis has been described as uncommon and usually associated with staphylococcal pneumonias. However, cavitory necrosis is most commonly encountered in children with *Streptococcus pneumoniae* infection.^{6, 12, 15} Only 41% of cases of cavitory necrosis identified on CT are seen on chest radiography.¹² Most children with cavitory necrosis are severely ill.^{12, 15} However, unlike in adults, in whom the mortality rate for cavitory necrosis is high and early surgical removal of the affected lung has been advocated,^{12, 15} the long-term outcome of children with cavitory necrosis is favorable with medical management alone¹² (see Fig. 53-8). Amazingly, in children with cavitory necrosis, follow-up radiographs obtained later than 40 days after the acute illness are most often normal, lacking any evidence of chronic scarring, persistent cavity formation, or other sequelae.¹²

Pleural Complications

The cause of persistent sepsis in a child who is being treated for pneumonia may also be related to a pleural complication. This is most often the unrecognized cause of sepsis, when previous intervention has been performed to treat a parapneumonic effusion. CT yields helpful information regarding the management of parapneumonic effusions, such as depicting a loculated pleural collection not in communication with a indwelling chest tube, poor chest tube placement, or failure of lung reexpansion.¹³ All of these findings suggest a need for a change in drainage strategy.

Finally, on chest radiography, it often is difficult to determine how much of an opacity is due to pleural effusion and how much is due to consolidated lung when each is present. Accurate determination by CT of the amount of pleural fluid also affects therapeutic decisions regarding drainage.¹³

CT Evaluation of Immunocompromised Children with Suspected Pneumonia

Children can be immunocompromised for a variety of reasons, including cancer therapy, bone marrow transplantation, solid organ transplantation, primary immunodeficiency, and acquired immune deficiency syndrome (AIDS). They represent a population who continue to increase in number. At most tertiary children's medical centers, the number of CT examinations of the chest performed in immunocompromised children far outnumber those performed in immunocompetent children.

Acute pulmonary processes are a common cause of complications and death in immunocompromised children.^{5, 41, 43} Because of the fragile condition of these patients, prompt diagnosis and treatment of pulmonary infections are imperative. When a pulmonary process is suspected on the basis of imaging, invasive diagnostic procedures such as bronchoscopy are performed or new therapies are empirically started.

Figure 53-7. Pneumatocele in a 3-month-old boy. CT scan shows large air-filled cavity (P) with thin walls in the left upper lobe. The surrounding lung parenchyma demonstrates no evidence of necrosis.

Figure 53-8. Cavitory necrosis in a 5-year-old boy with *Streptococcus pneumoniae* infection. A, Contrast-enhanced CT scan shows left lower lobe opacity (arrow) with multiple fluid-filled cavities with thin walls and lack of normal lung architecture. B, CT scan at more superior level (lung windows) shows air-filled cystic component (arrow). C, CT scan obtained 3 months later shows resolution of the cavities and only a linear band (arrow) of scarring that remains.

Regarding confirmation or exclusion of pneumonia, as in immunocompetent patients, chest radiography is the primary imaging modality. However, because of the poor condition of many of these patients and the risk associated with exposure to multiple persons, radiographic evaluation of these patients is often performed with portable equipment. Often these patients are not able to take deep breaths, rendering low lung volume radiographic examinations. The negative predictive value of such radiographs is low compared with frontal and lateral radiographs obtained at full inspiration.

Because of these factors, CT plays a greater role in detecting and excluding pulmonary infection. The detection of pulmonary abnormalities with CT is excellent.⁴¹ CT localizes high-yield areas for diagnostic procedures such as bronchoscopy and needle aspiration.

In immunocompetent children, the primary characterization of pulmonary infections is determining whether the infectious agent is bacterial or viral. In immunocompromised hosts, the issue is more complex. The array of agents that can cause aggressive infections is great and includes fungal infections such as *Aspergillus* and *Candida*, viral infections such as cytomegalovirus infection, and *Pneumocystis carinii*.^{5, 41, 43}

In addition, a variety of noninfectious pulmonary processes can present with acute or subacute clinical findings that mimic pulmonary infection,⁵ including alveolar hemor-

rhage, pulmonary edema, drug reaction, idiopathic pneumonia, lymphoid interstitial pneumonitis, bronchiolitis obliterans, bronchiolitis obliterans with organizing pneumonia, and chronic graft-versus-host disease.^{5, 41, 43} The CT findings of many of these entities are nonspecific, with overlap of the findings seen between different causes. However, the combination of certain CT findings, in conjunction with clinical findings, can be very suggestive of a specific diagnosis.

The exclusion of fungal infection is often the clinical indication for CT in these patients. The hallmark CT finding that is associated with possible fungal infection is the presence of nodules.^{3, 5, 30, 41, 43} These nodules are often clustered and can demonstrate any of the following associated findings: poorly defined margins, cavitation, or a surrounding halo of ground-glass opacity.^{3, 5, 30, 41, 43} (Fig. 53-9). Pathologically, the central nodular density on CT represents the actual fungal infection, and the surrounding halo represents hemorrhagic infarction caused by thrombosis secondary to vascular invasion by the fungus.³⁰ These findings are, however, nonspecific and can be seen with nonfungal infections such as cytomegalovirus infection.^{3, 5, 30, 41, 43}

CT Evaluation of Pulmonary Trauma

Trauma is the leading cause of death in children older than 1 year,⁵ with chest injury responsible for 25% of

Figure 53-9. Fungal pneumonia in a 17-year-old liver and kidney transplant recipient. CT scan shows large cavitary process containing an air-fluid level in the left upper lobe. Multiple clustered nodules are adjacent to the cavity.

pediatric trauma deaths.³⁷ There are a number of causes of lung consolidation in children who have undergone traumatic injury, including contusion, laceration, aspiration, atelectasis, and preexisting lung opacification as occurs from pneumonia.^{16, 28, 37}

The primary imaging modality in the evaluation of chest trauma is radiography. CT is uncommonly performed for the primary purpose of evaluating pulmonary trauma. However, when CT is being performed to evaluate traumatic injury to either the abdominal contents or the mediastinum, it is important to evaluate for lung contusion or other trauma-related lung opacity.

Lung contusion is defined as hemorrhage and edema formation in the alveoli and interstitium secondary to blunt chest trauma, without accompanying parenchymal laceration.^{16, 28, 37} The presence of lung contusion has been reported to be associated with an adverse effect on patient outcome.³⁷ In one study,³⁷ the mortality rate was 1.3% for pediatric trauma victims without lung contusions and 10.8% for those with contusions. Accurate identification of lung contusion and differentiation from other causes of lung opacification is helpful in planning the management of pediatric trauma patients.

On CT, lung contusions are characteristically nonsegmental in distribution and do not follow segmental or lobar anatomic boundaries^{16, 37} (Fig. 53-10). Contusions are usually located posteriorly (85%), have a crescentic (50%) or an amorphous (45%) shape, and are of mixed confluent and nodular quality (70%).¹⁶ The lung contusions of children may also demonstrate a 1- to 2-mm region of uniformly nonopacified subpleural lung that separates the area of lung consolidation from the adjacent chest wall¹⁶ (see Fig. 53-10). This finding is referred to as *subpleural sparing*; it is seen with many lung contusions and is not seen with other causes of airspace opacification and therefore is helpful in identifying contusions.¹⁶ The larger the lung contusion, the less likely subpleural sparing is to be present.¹⁶

Pulmonary laceration differs from pulmonary contusion; with a laceration, there is a frank tear within the lung parenchyma. The characteristic CT finding of pulmonary

Figure 53-10. Pulmonary contusion in a 12-year-old girl after a motor vehicle accident. CT scan shows characteristic findings of contusion, including posterior location, crescentic shape, nonsegmental distribution, and subpleural sparing (arrows).

laceration is the presence of an air-filled or a fluid-filled cavity^{28, 37} (Fig. 53-11). CT findings of atelectasis include a triangular shape, segmental distribution, and obvious signs of volume loss.^{16, 37}

Cystic Fibrosis

Image scoring systems have been used clinically and as a research tool to objectively evaluate the progression of

Figure 53-11. Pulmonary laceration in a 10-year-old girl who fell out of a tree. CT scan shows consolidation within the posterior right lower lobe with an associated parenchymal cavity (arrow) containing an air-fluid level.

Figure 53-12. High-resolution CT scan of patient with cystic fibrosis shows multiple sites of bronchiectasis and bronchial wall thickening. There is volume loss within the left upper lobe, demonstrated by medial displacement of the upper lobe bronchus (arrowhead).

lung disease in patients with cystic fibrosis.^{1, 2, 11, 33} The goal is to facilitate objective evaluation of existing and newly developed therapeutic regimens, such as gene therapy and mucolytic agents.^{1, 2, 11, 33}

Options in the pulmonary evaluation of patients with cystic fibrosis include chest radiography and high-resolution CT (HRCT).^{1, 2, 11, 33} HRCT and chest radiography are used to evaluate morphologic changes of cystic fibrosis to determine the severity of disease. Multiple studies have suggested that HRCT is superior to chest radiography in the evaluation of lung disease, such as bronchiectasis, peribronchial thickening, mucus plugging, and emphysema, in patients with cystic fibrosis.^{1, 2, 11, 33} (Fig. 53-12). Other uses of CT in the evaluation of the patient with cystic fibrosis include evaluation for pulmonary abscess in patients not responding appropriately to antibiotic therapy and evaluation before lung transplantation.

There has been concern that the morphologic changes seen on HRCT and chest radiography may not reflect early functional pulmonary disease.^{11, 17} Functional imaging may offer a more sensitive way to detect early changes of cystic fibrosis in patients with minimal disease.^{11, 17} Some authors have advocated the use of hyperpolarized helium 3-enhanced MRI in the evaluation of both functional ventilation and morphologic information¹⁷ (Fig. 53-13). However, results are preliminary.

Special Considerations in the Pediatric Mediastinum

Mediastinal Masses

The mediastinum is the most common location of primary thoracic masses in children. In addition, most mediastinal masses occur in children, not adults. As in adults, characterization of the location of the mass as anterior, middle, or posterior can focus the differential diagnosis of mediastinal masses (see Chapter 29).

By far, the mostly commonly encountered imaging issues in the anterior mediastinum are the normal thymus,

Figure 53-13. Hyperpolarized helium 3-enhanced MR image of the lungs in a patient with cystic fibrosis. *Left*, A fast spin-echo (TR, 2857; TE, 80) coronal image through the posterior lung shows minimal peribronchial thickening demonstrated as linear high-signal areas (small arrows). No other morphologic changes of cystic fibrosis are present. *Right*, MR image obtained after the patient was ventilated with a single breath of hyperpolarized helium 3 demonstrates the absence of ventilation throughout the majority of the upper lobes (arrows). High-signal areas represent ventilated lung. The high signal intensity on the left should be distributed throughout the lung.

which should not be mistaken for a mass, and lymphoma.²⁹ There are a large number of other potential but much less common causes of anterior mediastinal masses in children, including teratoma (and other germ cell tumors), thymoma, and multilocular thymic cysts seen in association with AIDS.²⁹

Middle mediastinal masses are less common than anterior or posterior mediastinal masses and are usually related to either lymphadenopathy or duplication cysts.²⁹

Lymphadenopathy can be inflammatory, most often secondary to granulomatous diseases such as tuberculosis or fungal infection, or neoplastic, secondary to metastatic disease or lymphoma.

Duplication cysts can be bronchogenic, enteric, or neuroenteric. These appear as well-defined masses that are cystic on cross-sectional imaging.

Neuroenteric cysts, by definition, have associated vertebral anomalies.

Pathologic processes related to the esophagus can also cause middle mediastinal abnormalities. Foreign bodies can erode from the esophagus on a chronic basis and cause a middle mediastinal mass. A dilated esophagus caused by achalasia or a hiatal hernia may also appear as a middle mediastinal mass on chest radiographs.

There are a number of causes of posterior mediastinal masses in children, including neural crest tumors, neurofibromas, lateral meningocele, diskitis, hematoma, and extramedullary hematopoiesis.²⁹ However, similar to how anterior mediastinal masses in older children are considered to be lymphoma, the working diagnosis for posterior mediastinal masses in young children is neuroblastoma until proven otherwise.

Two issues specific to the mediastinum of children re-

Figure 53-14. Normal thymus in a 6-month-old girl. Axial, T1-weighted MR image shows thymus (T) to be homogeneous in signal and to have convex margins.

quire further discussion: the normal thymus and neuroblastoma.

Normal Thymus

One of the most common areas of confusion in the imaging of children is related to differentiation of the normal thymus from pathologic processes. This confusion led to “thymic radiation” therapy in the first half of the 1990s and continues to cause diagnostic problems for those who infrequently image children.²⁵ The thymus has a variable appearance in both size and shape in children. In children younger than age 5 years, and particularly in infants, the thymus can appear very large. The thymus also has a variable configuration. Between 5 and 10 years of age, the thymus becomes less prominent radiographically, related to the decreased growth of the thymus in relationship to the growth of the remainder of the body. During the second decade of life, the thymus should not be visual-

ized as a discrete anterior mediastinal mass on chest radiography.²¹

Abnormality of the thymus (or anterior mediastinum) is suspected when the thymic silhouette has an abnormal shape or abnormal size for patient age. Displacement of the airway or other structures suggests an abnormality. On CT or MRI, the normal thymus should appear homogeneous in attenuation or signal, typically is quadrilateral in shape, and may have slightly convex margins²¹ (Fig. 53-14). Heterogeneity, calcification, and displacement of the airway or vascular structures indicate an abnormality. True pathologic masses of the thymus are actually quite rare in children.

Thymic rebound is another source of confusion concerning normal thymic tissue. After a patient has ceased receiving chemotherapy for a malignancy, it is normal for the thymus to “grow back” on serial CT examinations. This interval increase in soft tissue attenuation in the anterior mediastinum (Fig. 53-15) should not be considered abnormal when encountered on cross-sectional imaging.

Neuroblastoma

Neurogenic tumors (neuroblastoma, ganglioneuroblastoma, ganglioneuroma) are the most common mediastinal masses of childhood. Approximately 15% of neuroblastomas occur in the posterior mediastinum, most before 2 years of age.³⁶

Most neuroblastomas are visible on frontal radiographs of the chest as a posterior opacity. Erosion or destruction of the adjacent ribs is common. Calcifications are reported to be visible on chest radiography up to 25% of the time, although in my experience they have occurred less often.³⁶ Cross-sectional imaging with CT or MRI confirms the presence of the tumor and evaluates the extent of disease, particularly whether there is intraspinal extension.³⁶ Thoracic neuroblastomas carry a better prognosis compared with abdominal neuroblastomas (Fig. 53-16).

Figure 53-15. Thymic rebound in a 12-year-old boy treated with chemotherapy. A, CT scan at level of aortic arch obtained while the patient was on chemotherapy demonstrates a lack of soft tissue in the prevascular space. The central line is in place (arrowhead). B, CT scan at the same level obtained 3 months later, when the patient is no longer receiving chemotherapy, demonstrates an interval increase in the soft tissue (arrows) in the prevascular space. The rebounded thymus has a triangular configuration, and the central line is no longer present.

Figure 53-16. Neuroblastoma in a 1-month-old boy. *A*, Chest radiograph shows a soft tissue mass (arrows) overlying the region of the left hilum. The interspace between the left fifth and sixth ribs is larger than the contralateral interspace at the same level. This finding is indicative of chest wall involvement and highly suspicious for neuroblastoma. *B*, CT scan shows a slightly heterogeneous soft tissue mass (N) displacing the descending aorta from its typical paraspinal location. *C*, Axial, fast spin-echo MR image with T2-weighting (TR, 2500; TE 85) shows the mass (N) to have high signal intensity. The high signal intensity within the chest wall (arrow) documents the chest wall invasion. There was no evidence of invasion of tumor into the spinal canal on either examination.

Special Considerations in the Pediatric Chest Wall

The chest wall has a number of functions that, when altered, can result in a variety of pathologic processes. In children, the chest wall is unique in that it is primarily cartilaginous. This makes several issues different in imaging of the pediatric chest wall.

Normal Anatomic Variations

There is a great deal of variation in the configuration of the anterior chest wall in children.^{10, 18} One study¹⁰ showed that one third of children have some variation in the anterior chest wall, including asymmetry such as a tilted sternum, prominent convexity of an anterior rib or costal cartilage, prominent asymmetrical costal cartilage, parachondral nodules, or mild degrees of pectus excavatum or carinatum^{10, 18} (Fig. 53-17). The importance of recognizing these variations is that they not be mistaken for serious abnormalities on imaging studies. Familiarity with these variations and their frequency may obviate the need for costly imaging.

For example, when one of these variations is palpated by a parent or physician, the concern of malignancy can be raised and cross-sectional imaging requested.^{10, 18} In a previous study that reviewed CT or MRI examinations performed to evaluate children thought to have a chest wall mass, all of the palpable lesions that were asymptomatic were related to normal anatomic variations.¹⁸ Knowledge of the high frequency of such variations should be communicated to referring physicians and parents when imaging is being contemplated in a child with an asymptomatic chest wall “lump.”

Abnormalities of Chest Wall Configuration

The bony thorax provides a structural framework on which the function of the pulmonary system depends.⁷ The association between deformity of the thorax and the development of respiratory dysfunction is well described.⁴⁰ Abnormal configuration of the thorax can also cause obstructive airway disease.⁷ The space in the superior mediastinum is normally limited, confined by the manubrium and sternum superiorly and the vertebral column posteriorly.

Figure 53-17. Normal variation of the anterior chest wall, which may present as palpable, nontender lumps on physical examination and be referred for cross-sectional imaging to exclude a mass. *A*, Tilted sternum (*arrowhead*) with associated asymmetrical anterior convex left rib (*arrow*) is shown in a 5-year-old girl. *B*, Anterior convex rib (*arrow*) is shown on T1-weighted image (TR, 740; TE, 15) of a 7-year-old boy. *C*, Asymmetry size of right costal cartilage (*arrow*) is shown on CT scan of a 13-year-old boy. (From Donnelly LF, Frush DP: Abnormalities of the chest wall in pediatric patients. *AJR Am J Roentgenol* 173:1595–1601, 1999.)

Figure 53-18. Tracheal compression and severe pectus deformity are shown on T1-weighted MR images (TR, 830; TE, 11) of a 16-year-old boy with Marfan's syndrome. *A*, Sagittal image shows loss of normal thoracic lordosis and pectus excavatum, which is so severe that the xiphoid (*arrowhead*) abuts anterior aspect of spine. Compression of the trachea (*arrow*) at the thoracic inlet is caused by a narrow anteroposterior diameter. *B*, Axial image at the level of the thoracic inlet shows severe tracheal compression (*arrow*) between the manubrium and spine. (From Donnelly LF, Frush DP: Abnormalities of the chest wall in pediatric patients. *AJR Am J Roentgenol* 173:1595–1601, 1999.)

Figure 53-19. Ewing's sarcoma of the sternum in a 16-year-old boy. A, Lateral radiograph shows soft tissue mass (arrows) and permeative appearance and periosteal reaction of underlying sternum. B, Sagittal T2-weighted fast spin-echo MR image (TR, 2000; TE, 60) shows high-signal-intensity soft tissue mass (E) arising from and destroying the sternum. (From Donnelly LF, Frush DP: Abnormalities of the chest wall in pediatric patients. *AJR Am J Roentgenol* 173: 1595-1601, 1999.)

Abnormal thoracic configuration can result in further reduction in the volume of this space or in alteration in the anatomic relationship between the trachea and adjacent structures, resulting in compression of the trachea or main bronchi (Fig. 53-18). The most common locations of such airway compression include the trachea at the level of the thoracic inlet and the left main bronchus.⁷

Two of the most common abnormalities of chest wall configuration are pectus excavatum and pectus carinatum. Although the majority of problems resulting from these deformities are cosmetic, pectus deformities can cause chest pain, fatigability, dyspnea on exertion, palpitations, and restrictive lung disease.¹⁹ When the deformities are severe, surgical repair is often performed. Although the diagnosis is made visually and does not involve imaging, cross-sectional imaging with CT or MRI has been useful in demonstrating the anatomy of severe deformities (see Fig. 53-18) and in evaluating possible complications after surgical repair.¹⁹

Figure 53-20. Recurrent large-cell lymphoma involving the chest wall of an 11-year-old boy. CT scan shows soft tissue mass (L) arising from the sternum (arrowhead) with associated bony destruction.

Aggressive Focal Processes

The chest wall can be involved in a number of aggressive neoplastic and inflammatory processes in children. The most common malignant primary bone tumors that involve the chest wall are Ewing's sarcoma (Fig. 53-19) and Askin's tumor (primitive neuroectodermal tumor of the chest wall).^{8, 20} Other primary bone tumors, such as mesenchymal chondrosarcoma, fibrosarcoma (Fig. 53-20), and osteosarcoma, infrequently involve the chest wall.^{8, 20} Metastatic involvement by neuroblastoma, lymphoma (see Fig. 53-10), or leukemia is more common.^{8, 20}

On CT or MRI scans, all of these malignancies typically appear as nonspecific aggressive lesions. Other lesions that can present with aggressive appearing focal masses in the chest wall include osteomyelitis and Langerhans' cell histiocytosis. Vascular malformations such as venous malformations and lymphangiomas can also involve the chest wall. The appearance of vascular malformations on studies such as MRI is variable and depends on the composition of the malformation and on whether the lesions are of high or low flow.⁸

Hepatobiliary System

Ellen C. Benya

Computed Tomography

This chapter discusses the computed tomography (CT) and magnetic resonance imaging (MRI) appearances of pediatric diseases of the liver and biliary tree. CT is commonly used to evaluate the liver and biliary system in children. Routine CT imaging of the pediatric liver is performed after administration of intravenous (IV) contrast material, with precontrast imaging performed only in selected cases.

Many, but not all, centers exclusively use low-osmolality, nonionic IV contrast material for CT imaging in children. The volume administered for CT imaging is typically 2 to 3 mL/kg (up to 150 mL maximal volume).^{29, 44} Rapid injection to achieve peak hepatic enhancement during CT imaging can be safely performed with power injectors in children when secure IV access with a 24-gauge or larger-bore peripheral or central venous catheter is present.^{21, 29, 41} Prior to use, the catheter or central venous line should always be checked, with a rapid hand infusion of saline, for blood return through the line and for patency. Additionally, optimal positioning of the access device should be assured in all cases before use. The rate of contrast administration using a power injector varies from 0.5 to 2.0 mL/sec depending on the luminal diameter, length, and type of the catheter.^{21, 29, 43}

Imaging of the liver on helical CT scanners is timed to coincide with expected peak hepatic enhancement: either imaging is performed immediately after injection of contrast material²⁹ or a tracking device is used to trigger imaging when a threshold attenuation value has been reached in the liver.^{44, 52} Multiple helical CT images can be obtained during shallow breathing in the infant or sedated child or with breath-holding in the older child. Slice thickness ranges from 5 to 10 mm depending on patient size, with a pitch of 1:1 to 2:1.^{29, 41, 52} The advent of rapid imaging on helical CT scanners has significantly diminished the need to sedate children undergoing CT examination.

Magnetic Resonance Imaging

The use of magnetic resonance imaging (MRI) in the evaluation of the pediatric hepatobiliary system is increasing. In almost all children younger than 8 years, sedation is required to obtain motion-free MR images. Although sedation protocols vary from institution to institution, many utilize oral chloral hydrate for children younger than 2 years, and IV pentobarbital alone or in conjunction with other intravenously administered sedatives for children older than 2 years of age.¹⁵

The MRI sequences chosen for pediatric hepatic imaging are generally tailored to the individual patient. Routinely, T1 and T2 or fast spin-echo T2 with fat saturation sequences are performed to evaluate the liver. Following gadolinium contrast administration, additional T1-weighted images may be obtained. Although the likelihood of allergic reaction to gadolinium contrast medium is low, adequate venous access is required to eliminate the risk of contrast extravasation.

In addition to standard T1 and T2 sequences, gradient-recalled echo sequences and MR angiography and venography can supplement the assessment of the hepatic vasculature,^{16, 51} and MR cholangiography can yield diagnostic information about the biliary system.^{25, 35}

Developmental Anomalies of the Liver

Abnormal Position

Variations in hepatic development, including agenesis of a hepatic lobe and accessory hepatic lobes, are infrequently encountered. The location of the liver is normally below the right hemidiaphragm in the right upper abdomen. Alterations in hepatic position may occur in children with viscerotransposition abnormalities, situs inversus, and polysplenia and asplenia; in these children, the liver may be left-sided or horizontally positioned. Abnormal hepatic fixation leading to hepatic mobility, or a "wandering liver," has been reported.¹ Additionally, in children with diaphragmatic defects or eventration, a portion of the liver may reside in the right or left hemithorax.

Hepatic Cysts

Simple hepatic cysts are focal parenchymal lesions that are considered to be a congenital developmental anomaly. These cysts may be unilocular or multilocular and are typically lined with biliary epithelium.³⁴ They are usually small lesions detected incidentally during the course of abdominal imaging. Rarely, they become large and result in a palpable abdominal mass. Computed tomography reveals unilocular or multilocular low-attenuation lesions (usually less than 20 Hounsfield units), with internal septa when multilocular but without other peripheral or internal enhancement (Fig. 54-1).³⁴ On MRI examination, hepatic cysts may show low or high signal intensity on T1 sequences, depending on the character of their internal contents, and they typically show high signal intensity on T2-weighted images.³¹

Importantly, differentiation of simple hepatic cysts from

Figure 54-1. Hepatic cyst. CT image after administration of intravenous contrast material, revealing a large multiloculated hepatic cyst. The cyst has central low attenuation (arrow) with thin enhancing septations (curved arrows).

other cystic hepatic lesions, such as echinococcal cysts, bilomas, resolving hematomas, and mesenchymal hamartomas, is not always possible on CT and MRI.^{18, 34} When multiple cysts are discovered in the liver, an associated condition, such as polycystic kidney disease, von Hippel-Lindau disease, biliary atresia, Byler's disease, or Caroli's disease, should be considered.^{6, 17, 19}

Choledochal Cysts and Caroli's Disease

Choledochal cysts are a developmental malformation of the biliary tree with resultant focal or diffuse dilatation of the extrahepatic biliary system. The most common type of choledochal cyst is a fusiform dilatation of the extrahepatic common bile duct. Occasionally, extension of the dilatation into the right and left common hepatic ducts may occur.¹⁸

Children with choledochal cysts may present with a palpable abdominal mass, pain, and/or jaundice, or with a cystic mass detected on prenatal sonogram. Diagnostic workup usually consists of sonography and nuclear hepatobiliary scintigraphy. A CT examination, although not routinely used to assess choledochal cysts, if performed shows a low-attenuation, fluid-filled cystic lesion in the region of the porta hepatis (Fig. 54-2).¹⁸

Caroli's disease is a developmental biliary abnormality with focal or diffuse intrahepatic biliary duct dilatation; it may occur alone or in conjunction with congenital hepatic fibrosis. Numerous rounded and/or tubular low-attenuation foci in the liver and the region of the portal hilum on contrast-enhanced CT examination correspond to the abnormally dilated intrahepatic biliary ducts. An eccentrically positioned enhancing nodule, the fibrovascular bundle, may be detected in the dilated bile duct.³²

Congenital hepatic fibrosis related to autosomal recessive polycystic kidney disease (ARPKD) consists of portal

Figure 54-2. Choledochal cyst. CT of the upper abdomen reveals a large low-attenuation choledochal cyst (arrows) in the portal hilum of the liver. The gallbladder, visualized anteriorly, is displaced by the large choledochal cyst (open arrow).

tract fibrosis and biliary ductal plate malformation with an otherwise normal hepatic parenchyma.²⁷ There is considerable variability in the phenotypic expression of this inherited disease, with the severity of the hepatic component of this genetic disease often inversely related to the degree of renal disease present. On CT, the liver may appear macroscopically normal, or mild to severely dilated intrahepatic biliary ducts may be identified.²⁷ If dilated intrahepatic biliary ducts are present, the corresponding MRI scan reveals low-signal-intensity bile ducts or bile lakes on T1-weighted images, and these show high signal intensity on T2-weighted images (Fig. 54-3). The use of MR cholangiography to detect intrahepatic biliary dilatation in congenital hepatic fibrosis due to ARPKD has recently been described.¹⁹

Figure 54-3. Biliary dilatation related to congenital hepatic fibrosis associated with autosomal recessive polycystic kidney disease. T2-weighted MR image of the liver demonstrates numerous large, high-signal-intensity regions of biliary dilatation (arrows). (Courtesy of Dr. Cynthia K. Rigsby, Children's Memorial Hospital, Chicago.)

Hepatic Infection

Pyogenic Abscesses

The liver parenchyma may become infected with a variety of pathogens. The imaging appearance varies depending on the type of infecting organism. Pyogenic abscesses in the liver are rare, occurring more commonly in children with underlying immunodeficiency syndromes and less commonly in immunocompetent children with indwelling umbilical venous lines, penetrating or nonpenetrating trauma, or sepsis.^{20, 48} CT imaging to evaluate for intrahepatic abscesses requires the use of IV contrast material. Precontrast CT images are not routinely obtained.

Abscesses have a low-attenuation, central collection of fluid on contrast-enhanced CT; a peripheral rim of enhancement or septations may be present (Fig. 54-4).¹⁸ MRI of the liver is not typically performed for pyogenic abscesses.

Fungal Infections

Children with congenital or acquired immunodeficiency syndromes or those who are receiving immunosuppressive medications are at increased risk for hepatic fungal infections. Disseminated fungal infections may result in numerous microabscesses in the liver, with associated microabscesses frequently detected simultaneously in the spleen and kidneys. *Candida* and *Aspergillus* are the most frequent fungal organisms that cause hepatic microabscesses. On CT, these microabscesses are typically small (smaller than 1 cm) foci in the liver; peripheral enhancement may or may not be detected (Fig. 54-5).^{14, 49}

Viral Hepatitis

A diffuse hepatic infection can occur with a variety of viral agents including, but not limited to, hepatitis A, hepa-

Figure 54-5. Candidal abscesses. CT image in an immunosuppressed child reveals multiple small low-attenuation microabscesses (arrows) in the liver, with associated microabscesses in the spleen (open arrows).

titis B, hepatitis C, and non-A, non-B hepatitis. A contrast-enhanced CT examination performed on a child with acute viral hepatitis may appear normal or may reveal a nonspecific, mottled, heterogeneous pattern of hepatic enhancement, and thickening of the gallbladder wall.⁴⁹ With progression to chronic liver disease and cirrhosis, a small liver with nodularity and varices secondary to portal hypertension may be detected.

Cat-Scratch Disease

Unusual hepatic infections are occasionally encountered in the pediatric population, such as cat-scratch disease. In children with cat-scratch disease, CT reveals multiple low-attenuation foci in the liver, corresponding to necrotizing granulomas.³⁸

Benign Hepatic Neoplasms

Infantile Hemangioendotheliomas

Infantile hemangioendotheliomas are the most frequent hepatic neoplasm discovered in the young child, usually infants younger than 6 months of age.^{12, 23, 28} Infants with this benign vascular neoplasm may be asymptomatic or present with a palpable abdominal mass, high output congestive heart failure, coagulopathy secondary to platelet consumption, or liver dysfunction. Associated cutaneous hemangiomas may be detected in up to 45% of children with hepatic hemangioendotheliomas.¹²

On CT and MRI, the spectrum of imaging appearances varies from a single lesion to multiple hepatic lesions that may diffusely involve the liver. On precontrast CT images, hemangioendotheliomas are lower in attenuation than the adjacent normal liver parenchyma, and foci of calcification are seen in approximately 50% of lesions.²³

When the CT examination is performed with rapid bolus administration of IV contrast material, a pattern of early peripheral enhancement with subsequent central enhance-

Figure 54-4. Pyogenic abscess. Contrast-enhanced CT image shows a low-attenuation abscess in the left lobe of the liver with peripheral rim enhancement (arrows). Incidentally noted is a ventriculoperitoneal shunt tube (open arrow) in the subcutaneous tissues of the anterior abdominal wall.

Figure 54-6. Hemangioendothelioma. CT of the upper abdomen demonstrates a lesion in the left lobe of the liver (arrows) with peripheral enhancement and central low attenuation due to hemorrhage or necrosis within the hemangioendothelioma.

ment detected on delayed images is often seen.^{12, 23, 28} With larger lesions, an area of central necrosis or hemorrhage that remains low in attenuation is frequently observed (Fig. 54-6). Because of the high degree of vascular shunting through hemangioendotheliomas, it is common to see a significant diminution in size of the infrahepatic aorta, with a corresponding large caliber to the draining hepatic veins (Fig. 54-7).²⁸

On MRI examination, the lesions are typically hypointense with respect to adjacent liver parenchyma on T1-weighted images and hyperintense on T2-weighted images (Fig. 54-8).^{23, 26} When intratumoral hemorrhage has occurred within the hemangioendothelioma, high-signal-intensity foci may be detected on T1-weighted MR images. Gadolinium contrast enhancement on MRI examination mirrors the centripetal pattern seen on CT examination,

Figure 54-7. Hemangioendothelioma. CT of the liver shows the enlarged draining hepatic veins (arrows) in this infant with hemangioendothelioma.

with early peripheral enhancement followed by central and more uniform enhancement of the lesion.³³

Cross-sectional imaging with CT and/or MRI is utilized to assess location and extent of the lesion if surgical resection of the hemangioendothelioma is being considered in the symptomatic infant.⁷ Additional modes of treatment for this condition include the medical therapies, steroids or interferon, and embolization.⁴⁰ Occasionally, hemangioendotheliomas may regress without treatment.¹²

A vascular hepatic mass lesion to consider in the young infant besides hemangioendothelioma is an arteriovenous malformation of the liver. This may also be a cause of congestive heart failure, neonatal hepatomegaly, or anemia.⁸

Mesenchymal Hamartomas

Recent pathologic evidence suggests that mesenchymal hamartoma of the liver, once considered a developmental liver lesion,⁴² may in fact be a benign hepatic neoplasm.³⁶ Histologically, these lesions are composed of a mixture of bile ducts and mesenchymal tissue. Mesenchymal hamartomas are usually detected in children younger than 2 years who present with a palpable abdominal mass.⁴² Although most mesenchymal hamartomas are complex cystic lesions in the liver, those with a large stromal (mesenchymal) component can be partially or completely solid lesions.³⁹ Exophytic growth of mesenchymal hamartomas from the liver may occur.

On CT, the more common cystic form of mesenchymal hamartoma appears as a low-attenuation mass; enhancing septa may be seen (Fig. 54-9).^{42, 47} Lesions that are predominantly stromal have regions of enhancing solid tissue.

On MRI examination, the appearance of mesenchymal hamartomas depends on the composition of the lesion. Cystic mesenchymal hamartomas may show low or high signal intensity on T1-weighted images, depending on the amount of protein content in the cystic portion, and they usually appear as high-signal-intensity lesions on T2-weighted images.¹⁴ Septations are frequently detected as low signal intensity bands on T2-weighted MR images. Stroma-predominant lesions commonly show low signal intensity on both T1-weighted and T2-weighted images.³⁹ Treatment of mesenchymal hamartoma is usually surgical resection of the lesion, although some have advocated assessment by serial imaging after biopsy without removal.⁴

Focal Nodular Hyperplasia

Focal nodular hyperplasia (FNH) is a benign hepatic neoplasm that is not often seen in the pediatric population.^{11, 31} The typical clinical presentation is detection of an asymptomatic, palpable abdominal mass.^{3, 11} Pathologically, FNH is composed of nodules of hyperplastic hepatocytes and proliferating bile ductules surrounding a scar.¹¹ There is a broad spectrum of CT and MRI appearances for FNH in children, and the central scar is not always identified on images.¹¹

On contrast-enhanced CT images, FNH significantly

Figure 54-8. Hemangioendothelioma. A, T1-weighted MR image in an infant with multifocal hemangioendothelioma in the liver. Numerous hypointense foci are seen throughout the liver. B, On a T2-weighted MR image, these same foci are hyperintense.

enhances during the arterial phase of contrast administration; the degree of enhancement diminishes in attenuation during the venous phase, resulting in a lesion whose attenuation is similar to that of the adjacent normal liver parenchyma.¹¹ When visible, the central scar remains a linear or ovoid region of low attenuation on contrast-enhanced CT (Fig. 54-10).^{3, 11}

On MRI examination, FNH has been described as a hypointense to isointense lesion on T1-weighted and as an isointense to mildly hyperintense lesion on T2-weighted images.^{31, 39} The region of the scar is typically hypointense on T1-weighted images and hyperintense lesion on T2-weighted images; however, significant variability exists, and this appearance is not always present.¹¹

Adenoma

Hepatic adenoma is another benign hepatic mass lesion that is rarely detected in the pediatric population. Those children and adolescents with glycogen storage disorder type 1, those taking oral contraceptives, and those receiving androgen therapy for Fanconi's anemia are most likely to develop hepatic adenomas.¹⁴

The CT imaging appearance is nonspecific. On contrast-enhanced CT, a low-attenuation lesion can typically be identified.³⁷ However, because hemorrhage may occur and lead to presentation with symptoms of abdominal pain and/or hypotension, a heterogeneous attenuation of the mass

Figure 54-9. Mesenchymal hamartoma. Contrast-enhanced CT image of the liver demonstrates a large low-attenuation lesion (arrows).

Figure 54-10. Focal nodular hyperplasia. CT of the liver obtained during the early arterial phase of intravenous contrast administration reveals an enhancing mass in the left lobe of the liver (arrows) with a visible central scar of low attenuation (curved arrow).

and/or perihepatic or intraperitoneal fluid may be detected on CT.

On MRI, the appearance of hepatic adenomas is quite variable and nonspecific. More than half of hepatic adenomas have heterogeneously hyperintense signal on T1-weighted images, related to hemorrhagic necrosis, and a peripheral hypointense rim corresponding to the pseudocapsule of the adenoma may be seen in a third of patients.²

Malignant Hepatic Masses

The most common primary pediatric liver tumor identified is hepatoblastoma. Other malignant hepatic tumors that may occur in children include hepatocellular carcinoma (HCC), undifferentiated embryonal sarcoma, and biliary rhabdomyosarcoma. Primary malignant liver tumors occur less commonly in children than metastatic Wilms' tumor or neuroblastoma.

Hepatoblastoma

Hepatoblastoma usually produces a palpable mass in the child younger than 3 years. Abdominal pain and anemia are occasionally present. Children with Beckwith-Wiedemann syndrome and hemihypertrophy are known to have an increased risk for development of hepatoblastoma and other abdominal tumors, and they should have periodic screening abdominal ultrasound examinations.^{37, 40} When a hepatic mass is detected on physical examination and/or abdominal ultrasound, abdominal CT is performed to further characterize and stage the extent of liver involvement, and chest CT is performed to evaluate for the presence of pulmonary metastases. In up to 90% of children with hepatoblastoma, an elevated α -fetoprotein level is found, and thus serial testing of the α -fetoprotein level is useful for tumor surveillance.⁴⁰

CT reveals hepatoblastomas as unifocal or multifocal low-attenuation masses, with calcification present in up to 40% (Fig. 54-11). Tumor thrombus, when present, can be appreciated extending into the portal vein, the hepatic veins, or the inferior vena cava on contrast-enhanced CT (Fig. 54-12).

On MRI, hepatoblastomas usually demonstrate decreased signal intensity on T1-weighted sequences and heterogeneously increased signal on T2-weighted sequences. If there is intratumoral hemorrhage, foci of increased signal intensity on T1-weighted images may be seen.^{13, 14} MRI may help confirm or exclude suspected venous extension of the tumor. Cross-sectional imaging with CT and/or MRI is used to assess location and extent of the lesion; this can help determine the feasibility of surgical resection of the hepatoblastoma both prior to and after chemotherapy.^{7, 24} Curative treatment includes surgical resection if hepatic lobectomy or trisegmentectomy can be performed.

Hepatocellular Carcinoma

Hepatocellular carcinoma does not commonly occur in the pediatric population. The average age at diagnosis is

Figure 54-11. Hepatoblastoma. CT of a large unifocal hepatoblastoma shows a focus of calcification (*arrow*) in the heterogeneously low-attenuation mass (*open arrows*).

12 years, and underlying chronic liver disease is present in up to 50% of these children.¹⁴ HCC may be detected as solitary or multifocal low-attenuation masses on contrast-enhanced CT images (Fig. 54-13); changes caused by coexistent cirrhotic disease may be appreciated. On MRI, T1-weighted sequences show low-signal-intensity lesions and T2-weighted sequences typically show heterogeneously high-signal-intensity foci. In the subtype of fibrolamellar HCC, a central scar may be identified on cross-sectional imaging. This is, however, a nonspecific finding, as FNH and hemangiomas may also have central scars.

Undifferentiated Embryonal Sarcoma

Undifferentiated embryonal cell sarcoma is a rare tumor most often detected in older children or adolescents. Pre-

Figure 54-12. Hepatoblastoma. CT of the liver reveals multifocal hepatoblastoma with extension of tumor thrombus into the portal vein (*open arrows*).

Figure 54-13. Hepatocellular carcinoma. CT of a large unifocal hepatocellular carcinoma shows a large heterogeneous low-attenuation mass (*open arrows*) in the right lobe of the liver.

sensation usually occurs after discovery of a large, palpable abdominal mass. These tumors occur more commonly in the right than in the left hepatic lobe.

On CT, these malignant mesenchymal tumors are low-attenuation lesions that frequently have cystic-appearing components with regions of enhancing solid tissue (Fig. 54-14).⁹ On MRI, they may show low or high signal intensity on T1-weighted sequences, and they usually show heterogeneously high signal intensity on T2-weighted sequences.³⁹ Gadolinium enhancement of solid tissue is detected on T1-weighted sequences.⁹

Biliary Rhabdomyosarcomas

Rhabdomyosarcomas of the liver in children are rare malignant tumors arising in the biliary tree. These are low-attenuation lesions on CT and may occur in any segment

Figure 54-14. Undifferentiated embryonal sarcoma. Contrast-enhanced CT image of the liver demonstrates a large lesion in the right lobe of the liver (*arrows*) with heterogeneous low attenuation centrally and peripheral nodules of enhancing tissue.

Figure 54-15. Hepatic metastases secondary to neuroblastoma. Contrast-enhanced CT shows numerous low-attenuation hepatic metastases (*arrows*) in a child with neuroblastoma (*open arrows*).

of the liver. Biliary dilation or obstruction may be identified distal to the tumor.¹⁸ The MRI appearance of hepatic rhabdomyosarcoma has not yet been described.

Metastatic Disease

Secondary or metastatic lesions to the liver occur frequently in children with Wilms' tumor and neuroblastoma. On contrast-enhanced CT images, the primary Wilms' tumor or neuroblastoma (arising in the abdomen) is usually easily identified, with metastatic disease to the liver detected as multiple low-attenuation lesions of varying sizes (Fig. 54-15). Lymphoma and leukemia and other neoplastic processes can also lead to metastatic foci in the liver.

Hepatic Trauma

Liver injuries from blunt abdominal trauma in the hemodynamically stable child are best evaluated with contrast-enhanced CT examinations.^{22, 49} Currently, MRI plays no role in the detection of acute abdominal injury.

The CT appearance of hepatic injuries in children mirrors that seen in adults: hematomas appear as rounded foci of heterogeneous low attenuation on contrast-enhanced CT examination, and liver lacerations appear as simple or complex linear low-attenuation foci (Fig. 54-16). Subcapsular hematomas are detected as crescentic low-attenuation fluid collections adjacent to the liver parenchyma in a subcapsular location. Associated hemoperitoneum may be identified in the peritoneal cavity or retroperitoneal space.⁵⁰

The CT appearance of healing hepatic injuries and the time course for their resolution have been described.¹⁰ Delayed complications of hepatic injury in children, such as pseudoaneurysms, delayed hemorrhage, abscesses, bilomas, and biliary strictures, are rare.^{10, 45, 46}

Hepatic Vascular Disease

Portal Vein Thrombosis

Portal vein thrombosis in children may be associated with a history of indwelling umbilical venous lines, phlebi-

Figure 54-16. Hepatic injury. Contrast-enhanced CT image reveals a complex laceration (*arrows*) and hematoma (*open arrows*) in the liver, with an associated subcapsular hematoma (*curved arrows*). Hemoperitoneum is visible in the left upper abdomen adjacent to the spleen.

tis secondary to intra-abdominal infection, hypercoagulable conditions, or tumor extension, or it may be idiopathic.⁴⁹ Following portal vein occlusion, numerous venous collaterals may develop in the portal hilum as alternate routes of venous blood supply to the liver. This phenomenon is referred to as cavernous transformation of the portal vein.

CT reveals the characteristic appearance of cavernous transformation of the portal vein as a tangle of small, enhancing vessels in the region of the porta hepatis, and no normally enhancing portal vein is visualized.³⁰ The clinical sequela of portal vein occlusion is the development of varices, which may hemorrhage. MRI and MR venography can be used to further clarify the venous anatomy both outside and within the liver of the child with cavernous transformation of the portal vein (Fig. 54-17).

Budd-Chiari Syndrome

Budd-Chiari syndrome is a rare hepatic vascular disease that is occasionally detected in children. It is caused by

obstruction of the hepatic veins or the suprahepatic inferior vena cava by a web, stricture, or thrombus.

The CT appearance varies depending on the etiology. The enhancement pattern of the liver is mottled, with frequent sparing of the caudate lobe.⁴⁹ When present, a thrombus can be identified as a low-attenuation filling defect in the inferior vena cava or hepatic veins. MR venography is particularly well suited for detection of hepatic vein and inferior vena cava abnormalities leading to Budd-Chiari syndrome, as it is a noninvasive diagnostic technique that precludes the need for a conventional venogram.

Biliary Obstruction

The common causes of biliary obstruction in the pediatric population change with the age of the child. In the neonate or infant, obstruction of the biliary system may be caused by bile plugging, choledochal cysts, or biliary atresia. Ultrasound, rather than CT or MRI, is the cross-sectional imaging modality of choice in this population.¹⁴

In the older child or adolescent, biliary obstruction may be caused by calculi, previously unrecognized choledochal cysts, sclerosing cholangitis, adenopathy, or a pancreatic mass. In these children, CT or MRI may be performed after an ultrasound examination to further define obstructing neoplastic adenopathy or pancreatic masses.

Pediatric Liver Transplantation

Pretransplant Evaluation

Liver transplantation has become an accepted form of treatment of end-stage liver disease in children as well as in adults. In children, common causes of liver failure that result in a need for liver transplantation include biliary atresia, severe hepatitis, and metabolic disorders. In certain situations, hepatic neoplasms may be treated by liver transplantation. Size considerations and limited availability of organs may require children to receive whole or segmental liver transplants from cadaveric donors or segmental liver transplants from living related donors.⁵ A pretransplant

Figure 54-17. Cavernous transformation of the portal vein. A, Axial MR image reveals numerous small collateral veins in the portal hilum (*arrows*) with no normal portal vein visible. B, MRI venogram shows absence of the main portal vein. The hepatic artery (*arrows*) alone is visible entering the liver hilum. Large gastric varices (*curved arrows*) are present.

imaging workup is usually performed with ultrasound; it is performed less often with CT or MRI, unless liver transplantation is being considered in a child with a malignant hepatic neoplasm.

Post-transplant Complications

After liver transplantation, CT examinations are often used to evaluate for associated complications. Infection is common in this pediatric population and CT is the imaging modality of choice to assess for intrahepatic and extrahepatic abscesses. There may be multiple fluid-filled bowel loops related to the Roux-en-Y biliary anastomosis in the right upper quadrant that may not opacify after administration of oral contrast material and that can cause difficulty in the assessment of abscesses or bilomas in this region.⁵ After a segmental liver transplant, there may be a postsurgical change at the cut edge of the liver with subsequent calcification of the region with time.⁵

Vascular complications following liver transplantation are better assessed with Doppler sonography. However, if focal hepatic necrosis has occurred as a result of vascular compromise, a contrast-enhanced CT may reveal areas of diminished enhancement within the liver.

Biliary complications of hepatic transplantation include leaks and obstruction.²⁵ Biliary leaks or disruption at the anastomotic site occur more commonly in the early post-transplant period. On contrast-enhanced CT examination, a low-attenuation bile collection may be detected in the region of the biliary-bowel anastomosis following bile duct leak (Fig. 54–18). Biliary necrosis, frequently seen secondary to occlusion or compromise of the hepatic artery, may also lead to breakdown of the bile ducts, with formation of intrahepatic bilomas or bile lakes that appear as low-attenuation collections within the hepatic parenchyma.

Biliary obstruction is typically a later complication of

Figure 54–19. Biliary stricture following segmental liver transplantation. Contrast-enhanced CT image in a child who has developed a focal anastomotic stricture at the biliary-to-bowel anastomosis. Tubular low-attenuation structures (arrows) correspond to dilated intrahepatic biliary ducts. (Courtesy of Dr. Cynthia K. Rigsby, Children's Memorial Hospital, Chicago.)

hepatic transplantation. Stricture formation may occur at the anastomosis, with subsequent dilatation of the intrahepatic bile ducts, which may be identified on CT as tubular low-attenuation structures adjacent to the enhancing portal veins (Fig. 54–19). MRI cholangiography may further define the biliary anatomy and sites of obstruction in the pediatric liver-transplant patient.^{25, 35}

Post-transplant lymphoproliferative disorder (PTLD) associated with Epstein-Barr virus infection and immunosuppression may occur following liver transplantation. Macroscopic evidence of PTLD may not be visible on CT imaging. When such evidence is visible, it includes low-attenuation mass lesions in the liver¹⁴ and/or intraperitoneal and retroperitoneal adenopathy and pulmonary nodules.

Figure 54–18. Bile leak following segmental liver transplantation. Contrast-enhanced CT image in a child with a segmental liver transplant reveals an irregular, low-attenuation collection of bile (arrows) with foci of air following anastomotic leak at the biliary-bowel anastomosis.

Pediatric Spleen

Kimberly E. Applegate

Helical computed tomography (CT) is commonly used to investigate the spleen for injury, infection, infarction, and tumor and to determine spleen size and position.^{33, 34, 43, 50} Both the normal and the abnormal spleen are optimally imaged at CT using intravenous (IV) contrast (Fig. 55–1). There is a growing interest in using CT imaging guidance in the spleen for interventional procedures, including tumor biopsy, needle aspiration of cysts and infection, and abscess drainage.³⁶ The role of magnetic resonance imaging (MRI) in spleen disorders is not well defined, although there is some evidence of its use in the detection of fungal infection, systemic iron overload, tumor, and the heterotaxy syndromes.^{2, 9, 12, 13}

The normal spleen may demonstrate heterogeneous enhancement following IV contrast administration if there is a short scan delay time, a rapid injection rate, or severe cardiac or hepatic dysfunction. This appearance has been described as serpentine, cordlike enhancement.⁵⁸ IV contrast medium is hypothesized to enhance the white and red pulp of the spleen at different rates (Fig. 55–2).¹⁴

Normal Anatomy and Variants

Beginning in the 5th week of embryogenesis, the spleen develops as a mesenchymal mass within the dorsal gastric mesentery. It is the only alimentary tract organ that does not develop directly from the gut.¹¹ The spleen is a hematopoietic organ in the fetus and retains the potential for

hematopoiesis in the child and adult. For example, in chronic anemic conditions, the spleen may act as a hematopoietic organ similar to the liver. After birth, the spleen normally functions as a filter for abnormal red and white blood cells.⁴³ From 10% to 30% of humans have accessory spleens, usually located in the splenic hilum and typically measuring 1 cm.²⁹

The spleen has a number of mesenteric attachments, including the splenorenal, phrenicosplenic, and gastrosplenic ligaments. When these mesenteric attachments are either absent or more lax than usual, the spleen has the ability to move within the abdominal cavity. This rare entity, called “wandering spleen,” may be asymptomatic, may produce intermittent abdominal pain, or may present with acute abdominal pain when torsion occurs.^{4, 25, 32, 41, 42, 46, 48} The spleen may move from the left upper quadrant to the lower left or right side of the abdomen (Fig. 55–3). Torsion is more likely to occur in these cases, and children may present with acute abdominal pain and splenic infarction (Fig. 55–4). When infarction has occurred, the treatment is splenectomy; when symptoms are more chronic, splenopexy may be performed.²¹

Another rare congenital anomaly of the spleen, called *splenogonadal fusion*, occurs during the first trimester in utero, when the spleen fuses with the left gonad prior to normal ovarian or testicular descent at 9 weeks.¹¹ Some of the developing splenic tissue may migrate with the gonad into the pelvis or scrotum. In boys, cryptorchidism may be an associated finding. Because children with splenogonadal

Figure 55–1. Normal, homogeneous enhancement of the spleen. This helical CT image shows mild splenomegaly in a 12-year-old girl with a fever after bone marrow transplant. The two low-density lesions in her liver are the result of a fungal infection.

Figure 55-2. Heterogeneous enhancement of the normal spleen. Helical CT in a 10-year-old boy performed to evaluate for possible trauma shows the layered heterogeneous effect of short scan delay times. It is hypothesized that this appearance is caused by the difference in early contrast enhancement of the white and red pulp in the spleen.

Figure 55-3. Wandering spleen in an 18-year-old girl who presented with an abdominal mass. Helical CT image of the lower abdomen shows the ectopic position of the spleen on the left. The spleen is homogeneously enlarged from a mononucleosis infection. (Courtesy of Lynn A. Fordham, M.D., Chapel Hill, N.C.)

Figure 55-4. Acute infarction from torsion of the spleen in an 8-year-old girl with a 2-day history of left upper quadrant abdominal pain. Helical CT image shows complete lack of contrast enhancement of the enlarged, low-density spleen. Mesenteric edema and fat stranding can be visualized around the splenic vein (arrow).

Figure 55–5. Polysplenism in a 6-year-old girl with congenital heart disease. Three small spleens (*arrows*) are located in the left upper quadrant, and the two larger spleens contain multiple, tiny calcifications of uncertain etiology. Note the azygous continuation of the inferior vena cava (*arrowhead*) on the right, the bridging liver, and the left-sided stomach location (*open arrow*) ipsilateral to the spleens.

fusion are often asymptomatic, splenogonadal fusion is not discovered unless a mass is palpated in the scrotum or until it is incidentally identified at surgery.

The spleen is *always* located on the same side of the abdomen as the stomach regardless of abdominal situs. In situs solitus, the stomach and spleen are located in the left upper quadrant; in situs inversus, they are located in the right upper quadrant. In situs ambiguus, in which the thoracoabdominal organs may be disordered, the location of the stomach air bubble on the plain radiograph defines the expected location of the spleen if it is present. Children with ambiguous position of the abdominal and chest organs may have a normal spleen, multiple small spleens (Fig. 55–5), or absence of the spleen.

Polysplenism and asplenia comprise the heterotaxy syndromes, an overlapping spectrum of abnormalities with situs ambiguus.^{2, 60, 61} Typically, associated congenital heart disease, vascular anomalies, a bridging liver, and intestinal malrotation are present.^{10, 22, 35} Asplenia occurs more frequently in boys and as for boys more severe congenital cardiac and vascular anomalies. Polysplenism occurs more commonly in girls and is associated with less severe cardiac disease, azygous continuation of the inferior vena cava, and, rarely, biliary atresia.

Splenomegaly

The ranges of normal spleen size throughout infancy and childhood have been established.³⁸ As a rule, the maximum spleen length is 6 cm plus one third times the child's age in years and should not exceed 12 cm.⁵⁶ When the spleen is enlarged, the normally pointed tips become rounded or bulbous (see Figs. 55–1, 55–3, and 55–4), and the inferior margin may extend below the inferior pole of the left kidney.

There are many causes of splenomegaly, but the most common in children are chronic liver disease and the leukemias/lymphomas.⁵⁶ Other causes include viral infections

such as mononucleosis,²⁴ cat-scratch disease,³⁷ storage disorders such as Gaucher's disease,²³ collagen vascular diseases, inflammatory bowel disease, Langerhans' cell histiocytosis, and hemolytic anemias. Infants undergoing therapy sequester blood, producing splenic enlargement.²⁶ More commonly, children with sickle cell anemia may have splenomegaly in early childhood when there is splenic sequestration but later may undergo "autosplenectomy," leaving a small, densely calcified spleen (see Fig. 55–9).^{27, 57}

Splenic vein thrombosis and splenomegaly may develop in children with pancreatitis, but this occurrence is less common than in adults.⁵⁶ In developing societies, splenomegaly may be caused by parasitic infection, particularly hydatid disease.

Trauma

After blunt trauma to the abdomen, the spleen and liver are the most commonly injured organs in children.^{45, 51, 52, 54} Splenic injuries are similar to liver injuries and include a range of abnormalities from subcapsular hematoma to intrasplenic hematoma, laceration (Fig. 55–6), and devascularizing injury (Fig. 55–7). Contrast-enhanced CT imaging is highly accurate in identifying these injuries and remains the imaging modality of choice.^{51–55} Typically, CT imaging demonstrates single or multiple low-density regions that result from lack of normal enhancement.

To estimate the severity of injury, the Organ Injury Scale Committee of the American Association for the Surgery of Trauma has classified the CT appearance of splenic injuries.²⁸ The five grades are as follows:

1. Capsular tears less than 1 cm parenchymal depth, or subcapsular hematoma less than 10% surface area.
2. Capsular tears 1 to 3 cm parenchymal depth, subcapsular hematoma 10% to 50% surface area, or intraparenchymal hematoma less than 2 cm in diameter.
3. Capsular tears greater than 3 cm parenchymal depth, subcapsular hematoma more than 50% surface area,

Figure 55-6. Splenic trauma, a result of a motor vehicle accident, in a 16-year-old girl. Helical CT image of the spleen shows the laceration of the posterior aspect associated with decreased enhancement. There is some low-density fluid around the injured portion of the spleen.

or intraparenchymal hematoma greater than 5 cm in diameter.

4. Hilar laceration with more than 25% splenic devascularization.
5. Completely shattered spleen or hilar laceration with complete devascularization.

Although grading systems based on extent of injury at CT have been developed to predict clinical outcomes and the need for operative intervention,^{28, 53} CT grading of splenic injury does not correlate with the need for operative intervention.^{17, 18} Most children with splenic injuries do not require operative management. In contradistinction, when the CT study is normal, there is strong predictive value that the child will not need surgical intervention later.^{40, 55}

Hemorrhage is frequently associated with splenic injury and appears as low-density, perisplenic fluid or free fluid in the dependent portions of the abdomen and pelvis. A small proportion of children with splenic injury have extra-peritoneal hemorrhage into the anterior pararenal space.⁴⁴

The presence of free fluid at CT is associated with more severe splenic injury but does not predict the need for operative intervention or the need for transfusion.^{39, 40, 55}

Most small splenic injuries resolve at follow-up imaging in 2 to 4 months, but larger injuries may take up to 1 year.³ In one report, 30% of splenic injuries of all grades resolved at follow-up CT.⁵ Abnormal splenic findings at follow-up CT included clefts, small cysts, and segmental infarctions. The role of follow-up CT after splenic trauma remains unclear.¹⁵

Infarction

Spleen infarction results either from arterial or venous occlusion. The arteries supplying the spleen are end-arteries, leaving the spleen without an alternative blood supply if arterial thrombosis, thromboembolism, or injury occurs.^{43, 59} Single or multiple, wedge-shaped, low-density lesions in the spleen periphery are well demonstrated by

Figure 55-7. Iatrogenic injury resulting in complete splenic infarction. This CT image is from an 8-month-old boy who underwent surgical resection of a large neuroblastoma in the left upper quadrant. Helical CT image reveals no contrast enhancement of the spleen except for its rim, because of capsular artery supply. A liver hematoma can be visualized in the posterior right lobe (arrow).

Figure 55–8. Multiple splenic infarcts in a 13-year-old girl after bone marrow transplant for treatment of a desmoplastic round cell tumor of the abdomen. Helical CT image demonstrates the typical wedge-shaped, low-density areas of infarction in the spleen.

CT (Fig. 55–8). Global infarction may be characterized by a rim sign on a contrast-enhanced CT scan (see Fig. 55–7). It may be difficult to distinguish an infarct from an abscess at CT imaging.^{56, 58} On MRI scans, the appearance of splenic infarction is variable, depending on both the age and the degree of hemorrhage within it.^{1, 59} Remote splenic infarction has a variable appearance at CT. It may not be visible, it may show scarring with contour irregularity, or it may result in cyst formation. Global infarction may result in a small, densely calcified spleen (Fig. 55–9).

Infection

Abscesses in the spleen are unusual but can be seen after splenic trauma, as a result of septic embolism, and in immunocompromised children. Splenic abscesses are usually of low density and variable size at CT. In immunocompromised children, systemic candidiasis sometimes produces multiple, tiny, round, low-density abscesses in the

spleen, liver, and, less commonly, the kidneys (Fig. 55–10).¹⁶ Children undergoing chemotherapy for leukemia or children with acquired immunodeficiency syndrome (AIDS) are most commonly affected by multiple fungal abscesses. Children with AIDS are also at increased risk for mycobacterial abscesses in the spleen.

CT imaging may reveal multiple punctate calcifications in the spleen and liver in asymptomatic children (Fig. 55–11). These calcifications are usually caused by granulomatous disease such as chronic granulomatous disease, tuberculosis, histoplasmosis, or cat-scratch disease.^{8, 37, 49}

Cysts and Neoplasms

Splenic masses are rare—even the most common one in children, the cyst. Cysts may be either true epithelium-lined cysts or pseudocysts, which occur after infection, infarction, or trauma (Fig. 55–12).^{6, 7, 16, 19, 31} After IV contrast administration, cysts have a low density relative to

Figure 55–9. Remote infarction of the spleen in a 12-year-old girl after meningococcal sepsis. She had a remote history of bone marrow transplant for chronic myelogenous leukemia. Helical CT image reveals a diminutive, densely calcified spleen.

Figure 55-10. Candidiasis of the spleen in a 2-year-old boy with acute myelogenous leukemia undergoing chemotherapy. Helical CT image reveals the typical low-density appearance of numerous small abscesses in the spleen due to *Candida albicans* infection. Although the liver is typically coinfectd in candidiasis, there were no abscesses seen in this child's liver at CT examination. Multiple abscesses, however, were also seen in both kidneys at CT.

Figure 55-11. Granulomatous disease of the liver and spleen in a 10-year-old girl. Helical CT image reveals scattered punctate calcifications within the liver and spleen. The cause of the granulomatous disease was not known.

Figure 55-12. Incidental splenic cyst in a child with Crouzon's syndrome. Helical CT image shows a small, low-density, round cyst in the spleen (arrow). The cause of the cyst was unknown, and there is no known association with Crouzon's syndrome. The child also has a marked scoliosis deformity.

Figure 55–13. Hamartoma of the spleen in a 17-year-old boy with tuberous sclerosis. Coronal T2-weighted MR image of the abdomen shows a large heterogeneous-signal-intensity mass in the lower portion of the spleen in the left upper quadrant (arrows). Note the high signal intensity of a small renal cyst in each of the patient's kidneys (open arrows).

normal spleen. The most common infectious type is the hydatid cyst, caused by *Echinococcus* tapeworm infection. This cyst may be unilocular or multilocular and commonly affects children in developing societies.⁵⁹

Primary splenic tumors are exceedingly rare in children and are usually benign.²⁰ The most common benign tumor in children is the hamartoma (Fig. 55–13), followed by the hemangioma. Both are often asymptomatic. The hamartoma is usually a solid, solitary lesion of low or mixed low and high density, although it may appear partially cystic. The imaging appearance of the hemangioma in the spleen is similar to that in the liver. It is hypodense or isodense to the spleen without contrast material; after administration of IV contrast, it enhances homogeneously, appearing hyperdense, compared with the normal spleen appearance. Hemangiomas may be solitary or multiple. In rare instances, they are associated with a consumptive coagulopathy called the Kasabach-Merritt syndrome. Vascular and lymphatic malformations can occur in the spleen either in

isolation or in association with similar lesions at other body sites. Lymphatic malformations may appear as either unilocular or multilocular cysts.³⁰

Lymphoma and leukemia are the most common malignant tumors to involve the spleen in children. Unfortunately, CT cannot distinguish spleen involvement from noninvolvement. The involved spleen may be of normal size and show an enhancement pattern. When abnormal, the spleen most commonly shows homogeneous enlargement without masses. Four CT patterns of lymphomatous involvement have been described:

1. Homogeneous enlargement.
2. Miliary masses.
3. Macroscopic masses.
4. A large solitary mass.^{16, 47}

Typically, the masses are of low density compared with the normal spleen appearance, as visualized with contrast-enhanced CT (Fig. 55–14).

Figure 55–14. Lymphomatous involvement of the spleen in a 15-year-old boy. Helical CT image reveals two low-density lesions in the patient's spleen, which is mildly enlarged. The patient also had several low-density lesions in his right kidney (not shown) at presentation. Two weeks after institution of chemotherapy, the low-density lesions resolved completely and spleen size reverted to normal.

Pancreas

Carlos J. Sivit

Computed tomography (CT) has a primary role in the assessment of suspected pancreatic pathology in children. It is the modality of choice for evaluating suspected pancreatic neoplasms, trauma, or complications of pancreatitis. The use of helical CT scanning with thin collimation has allowed for the more precise delineation of many pancreatic conditions. In addition, magnetic resonance imaging (MRI) is being increasingly used to assess the pancreas in children, particularly in the evaluation of developmental or traumatic abnormalities of the pancreatic duct.

Normal Anatomy

The pancreas is located in the *anterior pararenal space*. Other anatomic structures in the same retroperitoneal anatomic compartment include the *duodenum*, the *ascending colon*, and *descending colon*. The pancreatic tail is in close proximity to the *splenic hilum*, which is peritoneal in location. The spleen contains a covering layer of peritoneum that is limited medially at the hilum, resulting in a bare area.²¹ This results in a potential two-way communication between the retroperitoneum and the greater peritoneal cavity. Thus, inflammatory or traumatic pancreatic conditions may be associated with the spread of fluid or inflammation into the peritoneal cavity, whereas splenic trauma that extends into the hilum may result in extension of blood into the anterior pararenal space that surrounds the pancreas.

Anterior to the anterior pararenal space that surrounds the pancreas is the *lesser sac*. This normally is a potential space that is an extension of the greater peritoneal cavity. The lesser sac connects to the greater peritoneal cavity through the foramen of Winslow. The boundaries of the lesser sac include the liver and stomach anteriorly, peritoneal reflections posteriorly, and the hilum of the spleen to the left.

Additional important anatomic structures in relation to the pancreas include the duodenum, which lies adjacent to the pancreatic head; the *inferior vena cava*, which lies posterior to the pancreatic head; the *portal vein* origin at the confluence of superior mesenteric vein and splenic vein, which lies posterior to the pancreatic neck; the *common bile duct*, which courses through the pancreatic head; and the *splenic vein* and the *splenic artery*, which run posterior to the pancreatic body and tail.

Developmental Abnormalities

Pancreas Divisum

Pancreas divisum is the most clinically important and common developmental abnormality of the pancreas. In

patients with this condition, the two pancreatic ducts (Wirsung and Santorini) are separate throughout their course. Normally, these fuse during development, with the main pancreatic duct of Wirsung forming from the ventral pancreatic duct and the distal portion of the dorsal duct. Pancreas divisum is associated with an increased incidence of pancreatitis.⁴ This is thought to arise secondary to partial obstruction to the passage of pancreatic exocrine secretions from the pancreas due to a narrowed orifice at the duodenum, resulting in the leak of pancreatic secretions into pancreatic tissue.

Magnetic resonance (MR) pancreatography is highly accurate in depicting the pancreatic ductal abnormalities in pancreas divisum.^{6, 8} The multiplanar capability of MR pancreatography allows visualization of the isolated ventral and dorsal ducts and of their entrance into the major and minor ampullae.

Annular Pancreas

An annular pancreas consists of an abnormal ring of pancreatic tissue surrounding the second portion of the duodenum. It is thought to be an abnormality in pancreatic development secondary to duodenal atresia. Thus, the primary abnormality is in the abnormal development of the duodenum. CT shows pancreatic tissue surrounding the second portion of the duodenum.¹⁰

Hereditary Diseases

Cystic Fibrosis

Cystic fibrosis is an autosomal recessive disease in which the majority of patients have severe exocrine pancreatic insufficiency. Pancreatic disease in these patients results from pancreatic ductal obstruction by inspissated secretions that leads to acinar and ductal dilatation and atrophy of acinar tissue.^{10, 24, 26} With the progression of fibrosis, there is eventual fatty replacement of the gland in many patients; less severe fibrosis may not result in fatty replacement. A correlation exists between the degree of fatty infiltration of the pancreas and the extent of pancreatic exocrine dysfunction present in these patients.²⁴

The CT appearance after fatty replacement of the pancreas includes a reduction in size of the pancreas with low-attenuation values equal to the fat noted within the gland^{10, 24, 26} (Fig. 56-1). Dystrophic parenchymal calcifications and cysts also may be noted.^{10, 11, 24, 26} Rarely, there can be complete replacement of the pancreas by macroscopic cysts, a condition described as *pancreatic cystosis*.¹¹

Figure 56-1. Fatty replacement of the pancreas in cystic fibrosis. CT scans through the body and tail of the pancreas (A) and through the head of the pancreas (B) in a patient with cystic fibrosis demonstrate diffuse low attenuation of the pancreas indicative of diffuse fatty infiltration.

Shwachman (Shwachman-Diamond) Syndrome

This is a rare congenital syndrome characterized by metaphyseal chondrodysplasia, short stature, bone marrow dysfunction, and pancreatic insufficiency. On CT scans, the pancreas is characterized by fatty replacement of the gland, similar to the changes seen in cystic fibrosis. With increasing fat replacement of the pancreas, a decrease in gland size is noted.

Von Hippel-Lindau Disease

Von Hippel-Lindau disease is an autosomal dominant disease characterized by retinal angiomas, cerebellar hemangioblastoma, and cysts in various organs, including the pancreas.¹⁰ Multiple pancreatic cysts are usually noted, which range widely in size. The cysts are seen primarily in the pancreatic body and tail. Occasionally, the cyst walls may calcify.

Infectious and Inflammatory Conditions

Acute Pancreatitis

Acute pancreatitis in children is most commonly seen after blunt abdominal trauma. Nontraumatic causes of acute pancreatitis include infection, drug toxicity, developmental anomalies, and hereditary pancreatitis. Acute pancreatitis can involve surrounding soft tissues and remote organs. The disease is classified as mild or severe on the basis of pathologic and clinical findings.

Mild acute pancreatitis is characterized pathologically by interstitial edema and rarely by microscopic foci of acinar cell necrosis.²⁰ Clinically, these patients may have abdominal pain and tenderness but few systemic signs. They generally demonstrate an improvement in clinical

signs and symptoms within 48 to 72 hours after the onset of illness.

Severe acute pancreatitis is characterized pathologically by fat necrosis, parenchymal hemorrhage, and pancreatic ductal disruption.²⁰ Patients may have severe clinical findings, including prolonged severe abdominal pain, gastrointestinal bleeding, disseminated intravascular coagulation, shock, and pulmonary insufficiency.

Acute pancreatitis may be associated with a number of complications, such as pancreatic necrosis, which consists of focal or diffuse zones of liquefied, nonviable pancreatic parenchyma; peripancreatic inflammation, consisting of soft tissue inflammation that surrounds the pancreas; acute focal or free extrapancreatic fluid collections; and pseudocysts, which represent focal fluid collections surrounded by a well-defined capsule of fibrous tissue.

Pancreatic necrosis tends to occur early in the course of the disease. The presence of pancreatic necrosis is predictive of severe pancreatitis and is the single greatest determinant of complications and death in patients with acute pancreatitis.² Focal fluid collections associated with acute pancreatitis may develop in the first few days after the onset of illness. These fluid collections may spontaneously resolve or evolve into pseudocysts.

A *pseudocyst* is a more mature fluid collection that characteristically takes at least 4 to 6 weeks to develop. Pseudocysts do not have an epithelial lining and hence are not true cysts.

Many cases of acute pancreatitis are successfully managed without the need for imaging. CT is commonly used in the evaluation of complications associated with severe acute pancreatitis because it is useful in diagnosing pancreatic necrosis and pseudocyst formation and in defining complex extrapancreatic spread of the inflammatory process.^{1, 2, 10, 13, 20, 26} Thin-collimation scanning is essential in the CT evaluation of the pancreas. The collimation should be between 2 and 4 mm, depending on patient size.

Optimization of intravenous contrast enhancement is also critical, with higher injection rates and dual arterial phase and venous phase scanning useful in detection of

Figure 56-2. Acute pancreatitis with pancreatic enlargement and ill-defined borders. CT scan through the pancreas in a patient with acute pancreatitis demonstrates diffuse pancreatic enlargement. There are ill-defined pancreatic margins secondary to peripancreatic inflammation.

hemorrhage or necrosis. Oral contrast opacification is also important not only for delineating the duodenum-pancreas interface but also because the spread of pancreatic inflammation may involve the small bowel mesentery as well.

CT findings associated with uncomplicated acute pancreatitis range from a normal appearing pancreas to diffuse gland enlargement^{13, 20, 24} (Fig. 56-2). The pancreas is reported to appear normal on CT in as many as 50% of all patients with acute pancreatitis.^{13, 20, 24} The pancreatic contour is usually smooth in mild pancreatitis and becomes more ill defined with increased severity of disease as the inflammatory process extends to involve the peripancreatic soft tissues (see Fig. 56-2). The gland demonstrates normal, homogeneous contrast enhancement in mild pancreatitis (see Fig. 56-2). Areas of decreased parenchymal enhancement are seen in severe pancreatitis associated with pancreatic necrosis.

The CT appearance of pancreatic necrosis consists of

Figure 56-4. Acute pancreatitis with fluid in the anterior pararenal space. CT scan through the pancreas in a patient with recurrent episodes of acute pancreatitis demonstrates fluid in the anterior pararenal space. There is a punctate parenchymal calcification in the head of the pancreas, likely secondary to prior inflammatory episodes.

areas of nonenhancing pancreatic parenchyma that involve 30% or more of the pancreatic volume^{5, 17, 25} (Fig. 56-3). As the devitalized tissue undergoes liquefaction, it gradually appears as an intrapancreatic fluid collection¹⁷ (see Fig. 56-3). Pancreatic necrosis may be complicated by infection. On CT scans, infected necrosis is characterized by air collections within nonenhancing or heterogeneous enhancing pancreas or adjacent soft tissues.

Acute fluid collections associated with acute pancreatitis may be seen on CT. Because these fluid collections are unencapsulated, they take the shape of the anatomic space in which they are located. These collections may be intrapancreatic or extrapancreatic. Extrapaneatic fluid collections occur more frequently than intrapancreatic collections. They may be seen in the retroperitoneum (Fig. 56-4), peritoneal cavity (Fig. 56-5), or mesentery.^{5, 13, 17, 18, 20, 25} The most common location of these fluid collections is the anterior pararenal space that surrounds the pancreas^{13, 25} (see Fig. 56-4).

Figure 56-3. Acute pancreatitis with pancreatic necrosis. A, CT scan through the pancreas in a patient with acute pancreatitis demonstrates a normal-appearing pancreas. B, Follow-up CT scan through the pancreas 48 hours later after clinical deterioration shows the absence of parenchymal enhancement in the body and tail of the pancreas, indicative of areas of pancreatic necrosis.

Figure 56-5. Acute pancreatitis with free peritoneal fluid. A, CT scan through the upper abdomen in a patient with acute pancreatitis demonstrates ill definition of the pancreatic margins and fluid in the anterior pararenal space. B, CT scan through the pelvis in the same patient demonstrates a large amount of free peritoneal fluid.

With extrapancreatic spread of the inflammatory process in severe pancreatitis, extensive inflammatory changes can be seen on CT throughout the abdomen and pelvis. In addition to the fluid collections described here, infiltration of peripancreatic and mesenteric fat may be noted. On CT, this appears as areas of stranding in the normally homogeneous low-attenuation fat (Fig. 56-6).

CT is useful in the follow-up of patients with acute pancreatitis to assess the development of pseudocysts. Pancreatic pseudocysts are round or oval on CT (Fig. 56-7). They are homogeneous in appearance, demonstrating fluid attenuation²⁵ (see Fig. 56-7). The pseudocyst wall ranges from barely perceptible to thick. Pseudocysts may be intrapancreatic (see Fig. 56-7) or extrapancreatic (Fig. 56-8) in location. Extrapaneatic pseudocysts develop more frequently in a retroperitoneal location in close proximity to the pancreas, but they may be seen anywhere in the abdomen or pelvis. Approximately 50% of all pseudocysts re-

solve spontaneously. Pseudocysts may be complicated by hemorrhage, infection, or rupture. Internal septations within the pseudocyst usually indicate prior hemorrhage (Fig. 56-9). The treatment of choice for persistent pseudocysts is percutaneous drainage.

Chronic Pancreatitis

Chronic pancreatitis is rare in childhood. The condition is characterized by irreversible damage to the pancreas from persistent or recurrent inflammation followed by fibrosis. In childhood, the most common cause of chronic pancreatitis is hereditary pancreatitis, a rare familial disorder.^{10, 26} Other causes include hyperlipidemia, hypercalcemia, sclerosing cholangitis, and trauma. The most common CT findings associated with chronic pancreatitis include pancreatic atrophy (Fig. 56-10) and parenchymal calcifica-

Figure 56-6. Acute pancreatitis with stranding of the mesenteric fat. CT scan through the midabdomen in a patient with acute pancreatitis shows diffuse infiltration of mesenteric fat.

Figure 56-7. Intrapaneatic pseudocyst. CT scan at the level of the pancreas in a patient with acute pancreatitis demonstrates a large pseudocyst originating within the body of the pancreas.

Figure 56-8. Extrapaneatic pseudocyst. CT scan through the upper abdomen in a patient with acute pancreatitis demonstrates an intraperitoneal pseudocyst posterior to the right lobe of the liver.

tions^{10, 26} (see Fig. 56-4). Pseudocysts are noted in approximately 5% of patients with chronic pancreatitis.

Trauma

Pancreatic injury is uncommon in children, accounting for approximately 6% of all solid viscus injury.²² Pancreatic injury is the most common cause of acute pancreatitis in childhood. Blunt force trauma is a more common mechanism of pancreatic injury than is perforating injury. The most common mechanism of injury is compression of the pancreas against the vertebral column.

The early clinical diagnosis of pancreatic injury may be difficult. Typically, there are few specific clinical symptoms, and laboratory data also are not helpful in the early diagnosis. Serum amylase and lipase levels may not rise for 24 hours or longer after the injury. In addition, elevated

Figure 56-9. Pancreatic pseudocyst with internal septations. CT scan through the upper abdomen in a patient with acute pancreatitis shows a large multiseptated pseudocyst in the left upper abdomen.

Figure 56-10. Chronic pancreatitis. CT scan through the pancreas in a patient with chronic pancreatitis demonstrates a small, atrophic pancreas.

serum amylase and lipase levels are commonly noted after blunt trauma in the absence of pancreatic injury.

The surgical classification of pancreatic injury is based on the extent of parenchymal injury and ductal disruption. The most widely used classification system is from the American Association for the Surgery of Trauma¹⁶ (Table 56-1). The main determinant of outcome severity is whether the main pancreatic duct is intact. Ductal disruption is associated with an increased prevalence of severe pancreatitis, pancreatic necrosis, hemorrhage, pseudocyst formation, and sepsis.

CT is the primary modality for the initial evaluation of suspected pancreatic injury in children. The CT-aided diagnosis of pancreatic injury can be difficult. The diagnosis is missed at CT in approximately one third of children with such injury.²² The difficulty involved in the CT scan diagnosis of pancreatic injury has several causes. Injuries may be missed because the pancreas is a small organ, and in children there is a relative paucity of surrounding retroperitoneal fat. Thus, delineation of the pancreatic margins and separation from surrounding bowel loops may be difficult. Also, when a pancreatic injury is present, there may be little separation of the fractured fragments secondary to organ elasticity (Fig. 56-11).

CT findings of acute pancreatic injury include direct visualization of low-attenuation laceration or fracture traversing the gland (Fig. 56-12), fluid in the anterior pararenal

Table 56-1. Pancreatic Injury Severity Scale

Grade	Description of Injury
I	Minor contusion or superficial laceration without duct injury
II	Major contusion or laceration without duct injury or tissue loss
III	Distal transection or parenchymal injury with duct injury
IV	Proximal transection or parenchymal injury involving the ampulla
V	Massive disruption of the pancreatic head

Figure 56-11. Pancreatic laceration with minimal separation of fracture fragments. Magnified CT scan through the pancreas of a patient injured in a motor vehicle accident shows a laceration through the body of the pancreas with minimal separation of the fracture fragments.

space (Fig. 56-13), fluid in the lesser sac, free peritoneal fluid, and thickening of the anterior renal fascia.^{7, 14, 22, 23} The best indicator of pancreatic injury on CT is unexplained peripancreatic fluid (fluid in the anterior pararenal space or lesser sac in the absence of visceral injury²² (see Fig. 56-13). Fluid in the anterior pararenal space may also dissect the pancreas and splenic vein, because the vein is only partially imbedded in the organ^{14, 23} (see Fig. 56-13).

Changes related to the development of acute pancreatitis after pancreatic injury, including gland enlargement, contour irregularity, and peripancreatic inflammatory changes, may be noted on follow-up examination. However, these changes are not present immediately after the injury. Post-traumatic pancreatitis may be complicated by all of the conditions listed in the discussion of acute pancreatitis.

Figure 56-12. Pancreatic laceration. CT scan through the pancreas in a patient who was assaulted shows a laceration through the tail of the pancreas.

Figure 56-13. Pancreatic injury with fluid in the anterior pararenal space. CT scan through the pancreas of a patient injured in a motor vehicle accident demonstrates peripancreatic fluid in the anterior pararenal space and fluid between the splenic vein and pancreas. No pancreatic laceration was visible on CT; at surgery, a pancreatic laceration was noted.

Neoplasms

Pancreatic neoplasms are rare in childhood. They are usually of epithelial origin and rarely of mesenchymal origin.^{9, 10, 26}

Epithelial Tumors

Epithelial pancreatic tumors may originate from endocrine or nonendocrine tissue. Most nonendocrine tumors are malignant, including pancreaticoblastoma, solid and papillary neoplasm, and adenocarcinoma. Although these are all rare tumors, pancreaticoblastoma is the most common of the three in childhood. It is typically seen in younger children. The CT appearance is that of a large, well-circumscribed, solid mass.^{10, 15, 26} There often is anterior extension of the tumor into the lesser sac.

The solid and papillary epithelial neoplasm is an uncommon low-grade malignancy. Metastases are rare. It is usually seen in young women, presenting most frequently in the second to third decades of life and thus may occur in adolescents. On CT, the appearance is that of a large, well-circumscribed, solid mass that typically originates from the pancreatic tail^{3, 10, 26} (Fig. 56-14).

Adenocarcinoma of the pancreas is extremely rare in children.¹⁹ The tumor is usually large at presentation and metastasizes aggressively. On CT, the tumor has a complex appearance with solid and cystic areas.¹⁹ Calcifications are occasionally noted within the tumor.

The epithelial tumors that originate from endocrine tissue are the islet cell tumors. They may be benign or malignant. Most are functioning tumors and include insulinoma, gastrinoma, vasoactive intestinal polypeptide (VIP)-secreting tumor, glucagonoma, and somatostatinoma.²⁶ These tumors often are not visualized on CT. If they are visible on a CT scan, their appearance is that of a

Figure 56-14. Solid and papillary epithelial neoplasm of the pancreas. CT scan through the pancreas demonstrates a large mass originating in the tail of the pancreas. The mass demonstrates decreased attenuation relative to the pancreatic body and tail.

small, enhancing, hyperdense mass. They usually measure less than 2 cm in diameter. In malignant islet cell tumors, lymphadenopathy and hepatic metastases may be present even if the primary tumor cannot be identified on CT.

Nonepithelial Tumors

Nonepithelial tumors may be primary to the pancreas or may secondarily involve the pancreas. The most common nonepithelial tumor of the pancreas in children is non-Hodgkin's lymphoma. The CT appearance of non-Hodgkin's lymphoma includes the presence of a focal intrapancreatic mass or diffuse gland enlargement²⁶ (Fig. 56-15).

Figure 56-15. Pancreatic lymphoma. CT scan through the pancreas in a patient with non-Hodgkin's lymphoma demonstrates a rounded, low-attenuation, solid mass in the head of the pancreas.

Typically, there is associated retroperitoneal and/or mesenteric lymphadenopathy and often other solid visceral involvement. Other rare nonepithelial tumors of the pancreas include the primitive neuroectodermal tumor and rhabdomyosarcoma.¹² They also appear as solid masses of varying sizes on CT.

Kidneys and Adrenal Glands

J. Michael Zerlin

Kidneys

Normal Anatomy

Both computed tomography (CT) and magnetic resonance imaging (MRI) generally provide excellent visualization of the kidneys, even in infants and younger children in whom there is relatively little perirenal fat. The kidneys lie within the retroperitoneum anterior to the psoas muscles. In infants and younger children, the longitudinal axes of the kidneys are roughly parallel to the spine. As the child grows, the psoas muscles enlarge and displace the lower renal poles anteriorly and laterally. As a result, the kidneys come to lie more obliquely in relation to the spine in the adolescent and adult. Anteriorly, the perirenal fat is bounded by Gerota's fascia, posteriorly by the fascia of Zuckerkindl, and laterally by the lateral conal fascia.

Computed Tomography

Renal parenchymal attenuation on nonenhanced CT scans is normally very homogeneous (32 to 60 Hounsfield units) with no visible corticomedullary differentiation.^{33, 40} The renal hilum and pelvis are usually visible; however, nondilated calices and infundibula are only occasionally visualized as subtle regions of fluid attenuation within the parenchyma. In older children and adults, the main renal vessels are often visible, even on nonenhanced studies, but it may not be possible to distinguish them from the renal pelvis in infants and younger children without contrast enhancement.

On postcontrast studies, renal parenchymal attenuation varies with (1) state of renal function, (2) dose of contrast material and rate of administration, and (3) timing of imaging in relation to administration of the contrast bolus.^{33, 40} After rapid administration of contrast material as a single intravenous (IV) bolus, the aorta and renal arteries are normally opacified first, followed by the renal veins and inferior vena cava. Renal cortical enhancement follows.

Corticomedullary differentiation is maximal during this phase, with the cortex appearing as 4- to 6-mm-thick peripheral bands of higher attenuation surrounding lower-attenuation medullary pyramids that are not yet enhanced. Thereafter, corticomedullary differentiation declines as medullary enhancement progresses and cortical enhancement wanes, until the renal parenchymal attenuation becomes more homogeneous. Once contrast material appears in the collecting system, renal parenchymal attenuation gradually declines.

Magnetic Resonance Imaging

On MR spin-echo T1-weighted images, the cortex has higher signal intensity than the medullary pyramids, and corticomedullary differentiation is, therefore, readily visualized. Corticomedullary differentiation on spin-echo T1-weighted MR images is most pronounced early in life and decreases with age.^{45, 81, 101} Corticomedullary differentiation is also more conspicuous on inversion recovery sequences and can be influenced by the patient's state of hydration. On very heavily T1-weighted images, however, the signal intensity of both the cortex and the medulla is lower and corticomedullary differentiation is thus reduced.¹⁷ Because infants and young children generally have less hilar fat than adults, the renal hilum is lower in signal intensity and less conspicuous early in life. By early adolescence, the appearance is similar to that in adults.^{17, 45} The renal artery and vein normally have very low signal intensity because of rapid blood flow in and out of the kidney^{81, 101}; when flow is slower, however, an intraluminal signal can occasionally be identified. This artifact can also be caused by flow-related enhancement when the vessels are imaged in cross-section.²¹ The collecting system and ureter have low signal intensity on spin-echo sequences because of the long T1 relaxation time of urine.^{45, 81}

The renal cortex and medulla both have increased signal intensity on T2-weighted sequences; however, the cortex is only slightly higher in signal intensity than the medulla. As a result, corticomedullary differentiation is less well visualized.^{45, 71} Perirenal fat appears bright on T2-weighted sequences, although somewhat less so than on spin-echo T1. Gerota's fascia appears as a low-intensity line separating the perirenal and pararenal spaces. A chemical shift misregistration artifact at the interface between the kidney and the adjacent perirenal fat occasionally produces the appearance of a low-signal-intensity line along one side of the kidney with a symmetrical high-signal-intensity line along the opposite side.¹⁴⁷ This artifact should not be misinterpreted as calcification.

Renal Anomalies

Most congenital renal malformations, including renal agenesis, renal ectopia, congenital obstructive uropathy, and multicystic dysplastic kidney, are fully evaluated with the following: (1) ultrasonography, (2) diuretic (MAG3) and cortical (DMSA) renal scintigraphy, and (3) voiding cystourethrography. The roles of CT and MRI in these disorders are generally restricted to more complex situa-

tions in which these modalities can provide clinically useful information that cannot be obtained noninvasively by other means. At CT, IV contrast material should be administered unless renal function is impaired sufficiently to contraindicate it.

MR T1-weighted images provide excellent visualization of most renal malformations.^{33,46} Imaging in the axial plane with either CT or MRI is usually sufficient. In fact, the site of fusion in horseshoe kidney or crossed-fused ectopia is often best visualized on axial images; however, direct coronal MRI imaging allows rapid evaluation of large areas of the abdomen and pelvis and can be particularly useful for identifying small, poorly functioning or nonfunctioning kidneys.

Ectopic Kidneys

Most ectopic kidneys lie caudal to the normal renal fossa—either lumbar or pelvic. In patients who have anterior abdominal wall defects (e.g., gastroschisis, omphalocele), the kidneys are occasionally located above the normal renal fossa. In patients with congenital diaphragmatic hernia, the ipsilateral kidney can be intrathoracic. In horseshoe kidney, both kidneys are low in position, with their lower poles joined by an “isthmus” composed of functioning parenchyma and fibrous tissue in variable proportions. In crossed renal ectopia, the ectopic kidney lies caudal and medial to the contralateral kidney, which is the normal position. The crossed ectopic kidney is usually fused to the

lower pole of the contralateral kidney; however, crossed ectopic kidneys can also be unfused. In either case, the ureter draining the ectopic kidney crosses the midline to insert on its proper side on the trigone (Fig. 57-1).

Renal Agenesis

In girls, unilateral renal agenesis is frequently associated with uterovaginal anomalies, such as agenesis, duplication, or atresia.¹⁵⁶ In boys, unilateral renal agenesis can be associated with an ipsilateral seminal vesicle cyst.⁹¹ The ipsilateral vas deferens and testis can also be absent, and testicular abnormalities, such as absence, cryptorchidism, and cystic dysplasia, can also be associated.¹⁹ Occasionally, CT or MRI reveals a small, poorly functioning or nonfunctioning kidney in a child who appears to have unilateral renal agenesis at ultrasound, IV urography, or renal scintigraphy. In such cases, the small kidney probably represents the remnant of an involuted multicystic dysplastic kidney, and a single ectopic ureter is typically present.⁷⁹ This appearance is not specific, however. In the absence of associated lower genitourinary anomalies, definitive information in the history, or previous imaging studies, differentiation from other causes of severe renal atrophy, such as renal infarction or reflux nephropathy, is not possible by imaging.

Upper-Pole and Single Ectopic Ureters in Girls with Incontinence

When a girl presents with incontinence characterized by persistent and incessant dampness, the most likely cause of

Figure 57-1. Right crossed-fused renal ectopia. *A*, Axial delayed postcontrast image through the lower abdomen. A small, irregularly shaped right kidney (RK) overlies the lower lumbar spine and extends toward the left side to fuse with the lower pole of the left kidney (LK). *B*, In the upper pelvis, the right ureter (arrow) is visible to the left of the midline, medial to the left ureter. *C*, In the lower pelvis, the right ureter (arrow) inserts normally into the trigone on the right side.

her wetting is an extravesical, ectopic ureter that inserts into the urethra, into the vagina, or onto the perineum. In most cases, the ectopic ureter drains the upper pole of a completely duplicated collecting system²³; however, the same clinical syndrome can also occur in a girl with a nonduplicated collecting system and ureter that drain to an ectopic orifice.^{66, 128} In boys, ectopic ureters do not cause incontinence because the ectopic ureter always inserts proximal to the urethral sphincter.¹⁶⁴

Despite the distinctive pattern of the incontinence in girls with this disorder, the diagnosis of ectopic ureter is, unfortunately, often not suspected, or the diagnosis is missed because the wrong imaging studies are requested or results are misinterpreted.²⁸ Because the upper pole that is drained by an ectopic ureter is often not dilated, it may not be visible on ultrasound examination. IV urography is usually diagnostic, but the findings can be subtle, especially when the offending upper pole functions poorly and cannot be directly visualized.¹⁵¹ When the ectopic ureter drains a nonduplicated collecting system, the kidney is small and dysplastic and functions very poorly, if at all. In this situation, the appearances at both ultrasound and IV urography are indistinguishable from unilateral renal agenesis. Arriving at a diagnosis can be even more difficult when the kidney itself is ectopic.⁶⁶ Delayed contrast-enhanced CT with thin sections through the kidneys, coronal T1-weighted MRI, and MR urography are the most sensitive modalities for identifying an occult ectopic ureter^{23, 28, 66} (Fig. 57-2).

Renal Infections

Acute Pyelonephritis and Renal Scarring

It is often difficult to differentiate upper from lower urinary tract infection in children on the basis of clinical and laboratory parameters alone.^{108, 124} The imaging diagnosis of acute pyelonephritis relies on the identification of anatomic changes secondary to inflammatory edema as well as segmental or lobar reduction in renal parenchymal perfusion and excretory function. Technetium 99m dimer-captosuccinic acid (DMSA) renal cortical scintigraphy, power Doppler ultrasonography, CT, and MRI have all been used to identify acute pyelonephritis in children who have fever and bacteriuria.^{37, 38, 104, 107, 135} All of these modalities are more sensitive than either conventional gray scale ultrasound or IV urography for the diagnosis of acute pyelonephritis.

On IV contrast-enhanced CT scans, acute pyelonephritis appears as one or multiple wedge-shaped or triangular areas of decreased parenchymal enhancement.^{100, 131} The anatomic distribution of the lesions is characteristically segmental, with a predilection for the renal poles^{80, 93} (Fig. 57-3). The affected areas appear edematous, with convex, rounded margins. Bulging areas of pyelonephritis that distort the renal contour can occasionally mimic intrarenal masses. When the infection is extensive, the kidney appears globally enlarged, although usually still reniform, with patchy enhancement of the less involved areas. Acute pyelonephritis is more difficult to diagnose on nonenhanced

Figure 57-2. Right duplex kidney with extravesical ectopic right upper pole ureter in an incontinent 7-year-old girl. *A*, Nonenhanced CT axial image through the upper poles of the kidneys. There is a contrast-urine level in a mildly distended right upper pole calyx (arrow) with minimal surrounding upper pole parenchyma. *B*, Contrast-enhanced CT axial image through the right renal hilum. The lower pole collecting system and proximal lower pole ureter are opacified. The mildly distended, nonopacified, proximal upper pole ureter (arrow) lies anterior and medial to the lower pole ureter. *C*, Contrast-enhanced CT, delayed axial image through the pelvis 20 minutes after contrast administration. The faintly opacified, distal right upper pole ureter (arrow) is posterior and medial to the lower pole ureter, which is very well opacified.

Figure 57-3. Acute multifocal pyelonephritis in a 6-year-old boy with bladder exstrophy and chronic bacteriuria. *A*, Contrast-enhanced CT axial image through the upper pole of the left kidney. A stellate region of nonenhancement can be seen in the anterior and medial aspect of the upper pole of the left kidney with a normal renal contour. *B*, Contrast-enhanced CT axial image through the lower pole of the left kidney. The region of nonenhancement extends inferiorly to involve the medial aspect of the lower pole of the left kidney. Again, the renal contour remains normal. *C*, Contrast-enhanced CT coronal reconstruction of the kidneys. The extent and distribution of the involvement of the medial portion of the left kidney is shown to greater advantage.

CT because the infected segments are usually isodense or only slightly hypodense in comparison to adjacent uninvolved parenchyma.¹³¹ On the other hand, localized parenchymal hemorrhage secondary to segmental venous obstruction (Fig. 57-4) occasionally produces increased attenuation within an area of acute pyelonephritis on non-enhanced CT.

The appearance of acute pyelonephritis at CT is not microbiologically specific.¹⁶⁸ The abnormal pattern of enhancement in the infected areas can persist for weeks or even several months after completion of antibiotic therapy, before resolving or progressing to scar formation.¹⁵⁰ The sensitivity of CT in acute pyelonephritis is comparable with that of DMSA and superior to that of combined power Doppler and conventional gray scale ultrasound. The ability of CT to differentiate between scars and areas of acute infection in the absence of a previous examination is a significant advantage over conventional DMSA. Because of the axial plane of imaging, however, milder degrees of asymmetrical reduction in renal parenchymal volume can be difficult to detect unless coronal reformatting is done.

The use of MRI for the diagnosis of acute pyelonephritis and renal cortical scarring has been studied in both piglets and humans.^{30, 104, 107, 123} On gadolinium-enhanced, fast spin-echo T2 and inversion recovery sequences, normally en-

hancing renal parenchyma has a much reduced signal intensity because of shortening of both the T1 and T2 relaxation times by the gadolinium. As a result, nonenhancing areas of acute pyelonephritis remain very bright in comparison with the lower signal intensity of normal renal parenchyma (Fig. 57-5). The sensitivity of MRI using fat-saturated T1-weighted and enhanced fast spin-echo sequences is comparable with that of planar DMSA renal cortical scintigraphy in detecting renal scarring. Suggestions in the literature that interobserver agreement in the diagnosis of both pyelonephritis and cortical scarring is better with MRI than with DMSA^{28, 104} remain to be confirmed. MRI does offer the advantages of multiplanar imaging and lack of ionizing radiation. Nonetheless, many younger children who undergo this procedure require sedation or even general anesthesia; consequently its routine use in infants and young children is limited.

Complicated Renal Infections

Renal abscesses and other serious acute complications of pyelonephritis, fortunately, are very rare in otherwise healthy children with acute ascending pyelonephritis.¹⁶⁷ These abscesses are more often encountered in children who have hematogenous pyelonephritis or who are immunocompromised or when the infection occurs in an ob-

Figure 57-4. Acute hemorrhagic pyelonephritis with progression to cortical scarring in a 3-year-old girl. Cultures of both urine and blood were positive for *Escherichia coli*. **A**, Nonenhanced CT of the kidneys. The left kidney is globally enlarged, with subtle, irregular regions of increased parenchymal attenuation anteriorly and laterally (arrows), representing areas of intraparenchymal hemorrhage. **B**, Enhanced CT of the kidneys. The left kidney is globally enlarged, with multiple large, irregular, low-attenuation, nonenhancing regions anteriorly and laterally (arrows), consistent with acute pyelonephritis. **C**, Enhanced CT of the kidneys 2 months later. The left kidney has decreased dramatically in size. The pattern of parenchymal enhancement on the left is now more normal. However, multiple clefts are visible along the lateral margin of the left kidney, consistent with evolving cortical scars, which were confirmed by ^{99m}Tc -dimercaptosuccinic acid (DMSA) cortical scintigraphy (not shown).

Figure 57-5. Right acute multifocal pyelonephritis. Gadolinium-enhanced coronal inversion recovery image through the kidneys. Multiple segmental zones of abnormally increased signal intensity are visible throughout the right kidney. The left kidney appears normal.

structed collecting system. Such serious complications are best evaluated with CT, which demonstrates both the intrarenal and extrarenal extent of the infectious process.^{111, 149, 150, 168} Abscesses can be either intraparenchymal or perirenal, and they usually appear as a central, low-density, nonenhancing cystic area surrounded by an enhancing wall. The distinction between uncomplicated acute pyelonephritis and abscess is important. The former is treated with antibiotics alone, whereas an abscess usually calls for drainage.¹⁴⁹

Renal Vein Thrombosis

In neonates and younger infants, renal vein thrombosis is usually associated with severe dehydration, hypotension, sepsis, or asphyxia.^{13, 40, 84} Premature infants and infants of diabetic mothers are at particular risk. In neonates with left adrenal hemorrhage, extension of thrombus from the left adrenal vein into the renal vein can lead to ipsilateral renal vein thrombosis. This is less common on the right, because the right adrenal vein drains directly into the inferior vena cava.

In neonates, renal vein thrombosis primarily involves smaller intrarenal veins, whereas the main renal vein and inferior vena cava frequently remain patent. In children with nephrotic syndrome, thrombosis can also arise primarily in the main renal vein or inferior vena cava, as in adults. In

patients with renal vein thrombosis, the affected kidney is enlarged and usually palpable in the flank. Gross hematuria is usually present, and hypertension is common. Renal vein thrombosis is usually unilateral; however, bilateral thrombosis does occur and results in severe acute renal insufficiency.

The diagnosis is usually made at sonography.¹¹² In the acute phase, the kidney is enlarged and edematous, with poor corticomedullary differentiation. Linear, echogenic bands radiating peripherally within the parenchyma represent thrombus in the interlobar and intralobular renal veins with surrounding perivascular hemorrhage. Occasionally, thrombus is also visible in the ipsilateral main renal vein and the inferior vena cava. Renal scintigraphy reveals markedly reduced or absent function. On follow-up, renal atrophy is a frequent but not an invariable result. Punctate, linear, or branching calcifications can appear over time within the thrombosed veins.^{84, 112} In cases of prenatal renal vein thrombosis, branching intrarenal calcifications and renal atrophy can be seen in the neonatal period. Alternatively, an older infant or child with severe renal infarction secondary to previously unrecognized neonatal renal vein thrombosis can present with the appearance of a small, echogenic, poorly functioning kidney that is sonographically indistinguishable from renal dysplasia.

The findings at CT closely correspond to those noted at sonography and scintigraphy.⁴⁰ Acutely, the affected kidney is enlarged and appears edematous. Perfusion is markedly reduced with inhomogeneous parenchymal attenuation and reduced or no function. If infarction results, areas of necrosis can progress to cyst formation. During the subacute and chronic phases, calcification within the thrombus and parenchymal atrophy can be seen.^{13, 40, 84}

In children with upper abdominal or lower thoracic neoplasms, renal parenchymal injury or infarction can occur secondary to the direct effects of the primary or metastatic tumor; from surgical trauma, chemotherapy, or radiation therapy; or from any combination of the two.^{2, 42} (Fig. 57-6). In some cases, the impact on the kidney can be

dramatic and devastating, resulting in obvious renal infarction or necessitating nephrectomy. More subtle parenchymal injuries may be manifested by impairment of renal growth or by more insidious renal atrophy.

Nephrocalcinosis and Nephrolithiasis

IV urography has long served as the primary imaging modality in patients with suspected acute urinary colic.¹²⁷ This modality is successful in precisely identifying the location of the offending calculus and in assessing the severity of the obstruction and its functional impact on the kidney. It is also useful in diagnosing preexisting obstructive uropathy and renal and ureteral malformations that might predispose to stone formation. Despite the simplicity and accuracy of IV urography, however, many calculi are not identifiable on plain radiographs. In addition, patients with ureteral colic frequently have severe pain, and the marked reduction in renal function caused by the acute obstruction can result in considerable prolongation of the study in some patients. There is also the potential for adverse reactions to the contrast material.

In recent years, noncontrast spiral CT has increasingly been used in place of the IV urography to investigate suspected urolithiasis.^{60, 144-146, 148} Noncontrast CT can be performed rapidly, and interpretation is usually straightforward. Reported sensitivity and specificity exceed 90%. Interobserver and intraobserver agreement in the interpretation of noncontrast CT is also reported to be very high.⁶⁵ Several reports have suggested that this modality is also effective in children.^{143, 155} Because the use of IV contrast material is avoided, the examination poses little risk of complication. CT also has the potential to provide useful diagnostic information even when the patient's pain turns out not to be caused by a calculus. The greater cost of CT, compared with that of IV urography, however, remains a challenge in many locations.

The study is performed without oral or IV contrast

Figure 57-6. Subacute radiation nephritis in a 5-year-old girl who had recent radiation therapy for an undifferentiated sarcoma of the posterior right eleventh rib. Contrast-enhanced CT axial images through the upper poles (A) and hila (B) of the kidneys. A very sharply defined, nonsegmental, homogeneously low-attenuation band of nonenhancement extends through most of the upper pole of the right kidney and the medial portion of the upper pole of the left kidney. There is also thickening of the soft tissues of the right lateral chest wall and over the lateral margin of the liver.

material. Contiguous 4- to 5-mm-thick axial images are obtained from the top of the kidneys to the symphysis pubis during a single breath-hold. In some very tall individuals, it may be necessary to obtain a second acquisition through the pelvis, but this is generally not required in children. Diagnosis relies principally on direct identification of the offending calculus within the ureter. Edema of ureteral wall—the “tissue rim sign”—and of the fat surrounding the ureter at the level of the impacted stone suggests the presence of a localized inflammatory reaction to the calculus.^{60, 90, 144} Edema of the ureterovesical junction can similarly be seen with calculi that are impacted within the submucosal tunnel. Perinephric stranding is an important observation indicative of obstruction, even in the absence of associated hydronephrosis or hydroureter proximal to the stone. After passage of a previously impacted stone, transient persistence of any or all of these findings occasionally provides an indirect clue to the diagnosis.⁶⁰

Abdominal radiographs and ultrasound are usually sufficient for the diagnosis of renal calculi, but non-contrast-enhanced CT can be very helpful in some patients whose kidneys are difficult to examine with ultrasound.⁴⁰ For example, in older patients with myelomeningocele or spinal cord injuries, visualization of the kidneys at sonography can be impeded by scoliosis or interfering bowel gas. Multiple, small calculi in ectopic kidneys, in horseshoe kidneys, or in severely hydronephrotic kidneys can be precisely localized with CT. Small calculi that fail to produce a posterior acoustic shadow at sonography are also readily identified at CT.

Renal Tumors

Wilms' Tumor

Wilms' tumor represents 95% of malignant genitourinary neoplasms in children and is the most common primary solid neoplasm in the pediatric abdomen.^{24, 165} The peak age at presentation ranges from 1 to 4 years. More than 90% of cases are diagnosed before age 8 years. Wilms' tumor is, however, rare in the first year of life.^{24, 46}

Most children present with a palpable abdominal mass. Other common findings include hematuria, fever, abdominal pain, and hypertension. Children with hemihypertrophy, sporadic aniridia, and Beckwith-Wiedemann syndrome are predisposed to developing Wilms' tumor, but they represent less than 5% of all patients with Wilms' tumor. Other more rare disorders associated with Wilms' tumor include Drash's syndrome and Perlman's syndrome. The risk of Wilms' tumor is also slightly increased in children who have genitourinary malformations such as hypospadias and ectopic or horseshoe kidney.^{9, 24, 43, 114}

Wilms' tumor is a malignant neoplasm arising from primitive, embryonal renal tissue.^{7, 35, 36} Most are solitary and can occur anywhere in the kidney. Multiple tumors occur in 5% of patients and are strongly associated with nephroblastomatosis. Bilateral tumors are usually synchronous; however, metachronous contralateral tumors can also occur, even many years after the original presentation.^{8, 9, 24, 35, 36, 132} Wilms' tumors grow rapidly and are usually very large at presentation. The mass is usually sur-

rounded by a well-defined pseudocapsule composed of compressed tissue.

Histologically, Wilms' tumors are classified as either “favorable histology” (>90% of cases) or “anaplastic.” Wilms' tumors with favorable histology present a “triphasic” appearance, with epithelial (tubular or glomerular), blastemal (small round cells), and stromal (spindle or myxoid) components in variable proportions and variable degrees of differentiation. Anaplastic Wilms' tumors occur at a slightly older age and have both a greater tendency for extending locally beyond the renal capsule into adjacent structures and a higher frequency of distant metastases. Hematogenous metastatic spread is most common to the lungs, liver, and central nervous system. Skeletal metastases are rare. Lymphatic spread to renal hilar and para-aortic lymph nodes can also occur. Intravascular extension into the renal vein and inferior vena cava occurs in 4% of children, and in 1% the tumor thrombus propagates into the right atrium.^{35, 36, 115} (Fig. 57-7).

Usually, ultrasound is the first imaging study performed in an infant or young child who presents with an abdominal mass. As a result, the diagnosis of Wilms' tumor is initially made upon ultrasound examination in most cases. Wilms' tumor appears as a hyperechoic, solid, intrarenal mass. The mass is often large, and it is usually predominantly solid, although it can contain cystic areas of necrosis and hemorrhage as well. Primarily cystic Wilms' tumors are rare.

On CT scanning, Wilms' tumor appears as a low-attenuation renal mass on nonenhanced scans. Postcontrast scans show a more inhomogeneous appearance, with variable enhancement of the solid components and no enhancement in areas of necrosis and cystic change. Calcification is unusual. Wilms' tumors containing small amounts of fat have been reported but are quite rare.^{62, 122}

On MRI scans, the mass typically appears inhomogeneous with relatively low signal intensity on T1-weighted sequences and bright signal on T2-weighted sequences. Solid areas enhance moderately after administration of gadolinium but much less so than normal renal cortex.^{12, 15, 17, 63, 88} Calcifications within the tumor appear as very-low-signal foci, and they are more difficult to recognize by MRI than by either CT or ultrasound.^{11, 14}

CT and MRI generally provide similar information regarding local tumor extent and regional adenopathy. Both modalities are superior to ultrasound for precisely defining tumor extent and staging.^{35, 129} (Table 57-1). Direct,

Table 57-1. National Wilms' Tumor Study Committee Staging System

Stage I	Tumor confined to the kidney with complete surgical resection
Stage II	Tumor outside the kidney with complete surgical resection
Stage III	Residual tumor below the diaphragm, or previous massive intraperitoneal spillage with no hematogenous metastasis
Stage IV	Distant hematogenous metastasis
Stage V	Bilateral renal involvement at the time of diagnosis

Status report, 1990: By the National Wilms Tumor Study Committee. *J Clin Oncol* 9:877-887, 1991; and D'Angio GJ, Breslow N, Beckwith JB, et al: Treatment of Wilms tumor: Results of the Third National Wilms' Tumor Study. *Cancer* 64:349-360, 1989.

Figure 57-7. Left Wilms' tumor with intravascular extension in a 2½-year-old girl who responded dramatically to 6 weeks of chemotherapy before nephrectomy.

A, Contrast-enhanced CT axial image through the kidneys. A large, predominantly solid, nonenhancing, left renal mass with enhancing parenchyma splayed around its periphery anteriorly and medially can be seen. Multiple small areas of focal necrosis are visible within the mass. A filling defect in the left gonadal vein (*arrow*) represents tumor thrombus.

B, Contrast-enhanced CT axial image through the liver. The intrahepatic portion of the inferior vena cava is distended with low-attenuation, nonenhancing tumor thrombus (*arrow*).

C, Contrast-enhanced CT axial image through the kidneys after 2 months of chemotherapy. The left renal mass is much smaller. The left gonadal vein (*arrow*) is well opacified and contains no residual visible tumor thrombus. Residual thrombus can be visualized in the inferior vena cava, however, and it enhances more inhomogeneously (*open arrow*).

D, Contrast-enhanced CT axial image through the liver after 2 months of chemotherapy. The intrahepatic portion of the inferior vena cava is now patent, and a small central filling defect represents residual thrombus (*open arrow*).

multiplanar imaging with MRI occasionally provides more detailed information when direct invasion of adjacent structures is difficult to confirm at CT.^{12, 76}

Careful evaluation of the contralateral kidney for tumor or nephroblastomatosis is mandatory. Unfortunately, nearly one third of synchronous contralateral tumors are not detected preoperatively. Although some authors have challenged the practice,⁹⁴ intraoperative inspection and palpation of the contralateral kidney are the generally accepted surgical standard, even when preoperative imaging studies show no abnormality in the contralateral kidney.^{35, 132}

Because of the propensity of Wilms' tumor to grow into the renal vein and inferior vena cava, these structures should be carefully evaluated for evidence of tumor thrombus (see Fig. 57-7). Identification of the cranial extent of the thrombus is critical in presurgical planning.^{35, 117, 159, 162} Intravascular extension can be more difficult to detect in some tumors that arise in the right kidney, particularly

when they are very large, because the right renal vein is very short. In addition, right renal masses frequently compress the inferior vena cava. Congenital variations in left renal vein anatomy—either retroaortic or circum-aortic—can also cause difficulty in patients who have left renal tumors. Flow-related artifacts in the inferior vena on contrast-enhanced CT⁶⁹ and axial gradient-echo MRI^{21, 51, 140} should not be mistaken for tumor thrombus.

Because of its low cost and its availability, and because the patient does not need to be exposed to ionizing radiation or iodinated contrast material, ultrasound is typically used for continued postnephrectomy surveillance; however, CT or MRI should be performed without hesitation if there is any question of recurrent or contralateral tumor.²²

Nephroblastomatosis

Nephroblastomatosis is the persistence of nonfunctioning, primitive, nephrogenic blastema in the kidney after

birth.⁷ Nephrogenesis is completed by the 34th to the 35th week after conception. No macroscopic blastemal remnants normally remain after this point, but microscopic blastemal remnants, or *nephrogenic rests*, are present in 1% of autopsies of newborns.

Anatomically, nephrogenic rests can be described as unifocal, multifocal, or diffuse.^{7, 163} Histologically, nephrogenic rests are described as perilobar or intralobar. Perilobar nephrogenic rests, which are located at the boundaries between the renal lobes, are more common than intralobar rests, which lie deep within the cortex or medulla. Perilobar and intralobar rests often coexist. Panlobar nephroblastomatosis is a rare condition in which both kidneys are nearly entirely replaced by nephrogenic rest tissue (Fig. 57–8).

The clinical importance of nephroblastomatosis lies in the potential for malignant transformation into Wilms' tu-

mor.^{7, 121, 163} Microscopic rests can remain dormant for long periods and then mature, sclerose, or enlarge to become macroscopic, hyperplastic, or neoplastic nodules. Hyperplastic nephrogenic rests can be difficult to distinguish from Wilms' tumor histologically. Although intralobar rests statistically have a much higher association with neoplastic transformation, malignancy can develop within perilobar rests as well. Histologically, 41% of patients with unilateral Wilms' tumor have nephroblastomatosis, compared with 99% of patients with bilateral Wilms' tumor.

Macroscopic nephrogenic rests appear hypoechoic at ultrasound and have low attenuation at CT.^{133, 163} A nodular, undulating renal contour may suggest nephroblastomatosis in at-risk patients even when discrete nodules are not identifiable. CT is generally more sensitive than ultrasound in detecting nephroblastomatosis, although some lesions that are visible at ultrasound are not seen at CT, and vice

Figure 57–8. Panlobar nephroblastomatosis with chemotherapy-induced remission and later recurrence with malignant degeneration into Wilms' tumor. The patient is a boy who presented at 15 months of age with marked abdominal distention.

A, Contrast-enhanced CT axial image through the kidneys at the level of the renal hila at the initial presentation. Both kidneys are markedly enlarged and almost entirely replaced by low-attenuation, nonenhancing, solid masses. Scattered strands of residual enhancing renal parenchyma are visible interspersed between the masses.

B, Contrast-enhanced CT axial image through the kidneys at the level of the renal hila 9 months later (after completion of chemotherapy). No residual tumor is visible. The kidneys appear normal.

C, Contrast-enhanced CT axial image through the kidneys at the level of the renal hila 20 months later. A small, low-attenuation, nonenhancing, solid peripheral nodule (arrow) measuring just less than 1 cm in diameter is now visible posteriorly in the mid right kidney.

D, Contrast-enhanced CT axial image of the kidneys at the level of the renal hila 1 year later. The peripheral nodule posteriorly in the mid right kidney has enlarged and now measures 2 cm in diameter (arrow). The nodule was resected and histologic examination confirmed malignant degeneration into Wilms' tumor.

versa.^{58, 72} Foci of nephroblastomatosis that sclerose and involute occasionally appear cystic. At MRI, nephrogenic rests do not enhance; they appear homogeneously hypointense, compared with the cortex, and isointense, compared with the medulla, on both T1-weighted and T2-weighted sequences.^{72, 133, 163}

In patients with Wilms' tumor, all visible macroscopic foci of nephroblastomatosis should be carefully identified on the prenephrectomy imaging studies and followed on subsequent examinations because these can indicate an increased risk of later contralateral tumor. Although some nephrogenic rests can be identified during intraoperative inspection and by palpation of the kidneys at the time of nephrectomy, many perilobar rests and most intralobar rests are not detectable in this fashion, including some that are visible at CT or MRI.³⁴ Microscopic foci of nephroblastomatosis are not detectable with any currently available imaging modality.

Patients with syndromes that are associated with nephroblastomatosis and Wilms' tumor^{9, 24, 43, 114} (e.g., hemihypertrophy, sporadic aniridia, Beckwith-Wiedemann syndrome) are screened with ultrasound during infancy and childhood. The frequency and duration of screening vary among institutions. We observe and follow patients every 3 to 6 months until the patient is 10 years of age, gradually lengthening the interval between studies as the child gets older.³ CT is used to evaluate suspected lesions that are identified at ultrasound. The expanded use of CT in screening children who are at risk for development of Wilms' tumor has increased the frequency of detection of smaller tumors.¹⁰²

Clear Cell Sarcoma

Once described as a Wilms' tumor variant, clear cell sarcoma is now accepted to be a separate disease, accounting for 5% of renal tumors in children. The peak incidence is between 3 and 5 years of age. As with Wilms' tumor, most children with clear cell sarcoma also present with a palpable abdominal mass. Clear cell sarcoma is distinguished from Wilms' tumor by its greater tendency for early hematogenous metastases, particularly to bone (rare in Wilms' tumor), and its generally much poorer prognosis.^{8, 97, 116} Clear cell sarcoma is not associated with nephroblastomatosis, hemihypertrophy, or aniridia.

Ultrasound, CT, and MRI reveal a predominantly solid, although frequently complex, renal mass with imaging features that are usually indistinguishable from Wilms' tumor.⁶⁸ Well-defined areas of cystic necrosis are frequent. Skeletal metastases are suggestive of clear cell sarcoma and can be present at diagnosis or appear later.⁹⁷ Skeletal metastases are usually osteolytic, although osteoblastic metastases do occur. On bone scans, both hot and cold defects occur.

Malignant Rhabdoid Tumor

Malignant rhabdoid tumor is the least common and the most uniformly deadly of the primary malignant renal tumors that occur during childhood.^{158, 159} Rhabdoid tumor occurs at a younger age than Wilms' tumor, with most cases presenting during the first year of life. A distinctive feature of this tumor is its association with synchronous or asynchronous primary tumors of the central nervous sys-

tem.²⁰ These tumors, which are histopathologically diverse, include primitive neuroectodermal tumor, ependymoma, and astrocytoma. Malignant rhabdoid tumor can metastasize to the central nervous system. Skeletal metastases also occur.

Ultrasound, CT, and MRI show a large, infiltrating, solid mass. The mass often arises centrally within or adjacent to the renal hilum¹⁴² and expands in a lobular fashion invading and compressing the surrounding parenchyma. Calcification is common and is usually linear. In some cases, the calcification outlines distinct tumor lobules. Crescentic subcapsular fluid collections around the periphery of the mass are considered to be suggestive of this disease and frequently indicate extrarenal extension. Because of its association with both primary and metastatic brain tumors, CT or MRI of the brain should be performed whenever the diagnosis of malignant rhabdoid tumor is suspected.

Renal Cell Carcinoma

Fewer than 0.5% of renal cell carcinomas occur in people under 20 years of age. The mean age at presentation for children with renal cell carcinoma is 11 to 12 years, which is considerably older than is typically the case with Wilms' tumor. Children with renal cell carcinoma that is limited to the kidney and that is completely resected have a relatively good prognosis; however, if the primary resection is incomplete or there is distant metastatic spread, the prognosis is poor.

The histopathologic and imaging features of renal cell carcinoma in children are similar to those in adults⁸⁷ (Fig. 57-9). The tumor usually appears hyperechoic at ultrasound and hyperdense at CT, although tumor enhancement after contrast is frequently less intense in children. Calcification is present in 5% to 10%.

Leukemia, Lymphoma, and Lymphoproliferative Diseases

Although infiltration of the kidneys is evident histologically in most children who die with leukemia or lymphoma, clinical or radiographic evidence of renal involvement is uncommon during life.⁴ Renal involvement is usually detected incidentally during staging or follow-up imaging studies in patients with disease elsewhere in the abdomen. Much less often, renal involvement precedes other manifestations of the disease, in which case the patient presents with a palpable mass, hematuria, or reduced renal function. Renal involvement in both leukemia and lymphoma is almost invariably bilateral, although it can be asymmetrical.

Renal lymphoma is usually of the non-Hodgkin type—Burkitt's lymphoma is most common—and associated with disease arising outside the urinary tract.^{4, 138, 160} Primary lymphoma of the kidney is rare. Early in the disease, tumor involves primarily the interstitium, sparing the nephrons themselves, and gross renal morphology is usually preserved. Later, as the neoplastic cells coalesce to form larger, expansile masses, irreversible nephron damage ensues and the renal architecture becomes disrupted.

Leukemic infiltration of the kidneys is usually characterized by diffuse bilateral renal enlargement. The normal reniform shapes of the kidneys are usually preserved, al-

Figure 57-9. Renal cell carcinoma of the left kidney in a 13-year-old girl. *A*, Nonenhanced CT axial image through the kidneys. A 6-cm solid mass arises from the lower pole of the left kidney. Numerous punctate and stippled calcifications are visible within the mass. *B*, Contrast-enhanced CT axial image through the kidneys. The mass in the lower pole of the left kidney is better demarcated from adjacent uninvolved renal parenchyma after contrast administration. The multiple small calcifications within the mass are again visible.

though the normal corticomedullary architecture is disrupted. Bilateral, focal masses that distort the collecting system and renal contours are more common in lymphoma, but both patterns can be seen in either leukemia or lymphoma. CT is superior to ultrasound for detecting renal involvement with lymphoma in children.^{138, 160} At ultrasound, the involved portions of the kidneys appear slightly hypoechoic, with diminished or absent corticomedullary differentiation. At CT, the involved areas are homogeneously low in attenuation and do not enhance (Fig. 57-10). Perirenal extension and renal hilar and retroperitoneal lymph node involvement also can be demonstrated.

Lymphoproliferative disorders represent an important group of potentially life-threatening conditions that occur in patients with severely impaired or suppressed T-lymphocyte-mediated immunity. These disorders can occur as a complication of immunosuppressive therapy for organ transplantation,^{49, 118, 126} in patients who have primary im-

munodeficiencies,⁴⁹ and in patients who have acquired immunodeficiency syndrome (AIDS).¹⁶⁸ Regardless of the underlying cause of the immunodeficiency, Epstein-Barr virus-mediated induction of polyclonal B-lymphocyte proliferation is critical in the pathogenesis of this disorder.^{103, 118}

Lymphoproliferative disorders are associated with lymphadenopathy, focal parenchymal masses, and diffuse infiltration of solid organs. The disease can be focal, multifocal, or widely disseminated, and any organ or body space can be involved. The gastrointestinal tract, solid abdominal organs, and abdominal lymph nodes are most often affected. Renal involvement occurs in 17% to 20% of cases.

Mesoblastic Nephroma

Congenital mesoblastic nephroma, or congenital fetal renal hamartoma, occurs almost exclusively in the first year

Figure 57-10. Burkitt's lymphoma with renal involvement in a 3-year-old boy. *A*, Contrast-enhanced CT axial image through the kidneys. Both kidneys are massively enlarged and almost completely replaced by multiple, low-attenuation, nonenhancing solid masses. *B*, Contrast-enhanced CT axial image through the kidneys 8 months later. The renal masses are no longer present and the kidneys are now normal in size. However, the renal margins are now irregular and somewhat lobular.

of life, and it is the most common solid renal tumor in the newborn.^{18, 29, 75} Most patients present with a palpable abdominal mass. Hematuria, hypercalcemia, abdominal pain, and hypertension also occur. The tumor is occasionally discovered prenatally. Once believed to be a congenital variant of Wilms' tumor, mesoblastic nephroma is distinguished by its occurrence at an earlier age, its generally benign course and limited growth potential, its derivation from predominantly mesenchymal derivatives, and its lack of a malignant epithelium.

The "typical" form of mesoblastic nephroma—representing approximately 60% of cases—appears as a firm to hard, pale yellow to gray solid tumor with no cysts or areas of hemorrhage or necrosis.^{18, 29, 75} Histologic examination reveals uniform spindle-shaped cells arranged in bundles with low cellularity and no cellular atypia. Although the renal capsule is frequently penetrated by strands of tumor extending radially into the perirenal fat, adjacent organs are not involved.

The "atypical" form of mesoblastic nephroma tends to be larger and more cellular, with a disorganized histologic appearance. Macroscopic areas of hemorrhage and necrosis produce a multicystic appearance. The tumor can invade adjacent organs and encase the inferior vena cava and renal vessels, but it is distinct from Wilms' tumor in that intravascular extension does not occur. Local recurrence after nephrectomy is unusual and is generally limited to tumors with "atypical" histology. Several well-documented cases of atypical mesoblastic nephroma metastasizing to lung and brain have been reported, but this is undoubtedly very rare.¹³⁷ Chemotherapy is indicated only when the surgical resection is incomplete or there is metastatic disease, regardless of the histologic appearance.

At ultrasound, mesoblastic nephroma appears as a large, solid renal mass that often replaces much of the renal parenchyma^{18, 29, 75} (Fig. 57–11). The mass can be either homogeneous or complex. Cysts are present in 60%, and small, scattered foci of calcification are occasionally pres-

Figure 57–11. Congenital mesoblastic nephroma in a 1-day-old male infant. Contrast-enhanced CT axial image through the kidneys. Enhancing renal parenchyma is visible splayed around the posterior and inferior margins of a very large, partially necrotic mass arising from the upper pole of the left kidney.

ent.⁵⁹ Tumors that obstruct the renal pelvis produce hydronephrosis.

On CT scans, the tumor presents as a nonenhancing, low-attenuation mass within which scattered islands of enhancing residual normal parenchyma may be seen.^{29, 75}

Multilocular Cystic Nephroma

Multilocular cystic nephroma is a benign, cystic tumor of the kidney that occurs primarily in infant boys between 3 months and 4 years of age and in middle-aged women.^{5, 86, 106} The tumor is frequently palpable. Hematuria, flank pain, and hypertension are also common findings. The tumor is usually solitary, but multiple synchronous tumors can also occur.

The tumor can involve part or all of the kidney. Grossly, it is composed of multiple, noncommunicating cysts of varying size, with intervening septa consisting of a mixture of fibrous tissue, tubular elements, and immature blastemal tissue. Rarely, rests of cells that are histologically similar to Wilms' tumor—so-called Wilms' tumorlets—are identified in the walls of the cysts; however, multilocular cystic nephroma appears to have no potential for malignant transformation. Nephrectomy usually results in cure, and local recurrence is rare after complete resection.

The imaging appearance of multilocular cystic nephroma is distinctive.^{47, 106} The tumor appears as a complex, multicystic mass. The septa between the cysts are characteristically thin and can enhance in some cases. The septa are frequently demonstrated to greater advantage with ultrasound than with CT. Thicker septations with irregular, solid areas of nodular thickening should suggest another diagnosis, such as cystic Wilms' tumor.⁸⁶ Curvilinear septal calcifications are occasionally present in adults. At MRI, the capsule surrounding the cystic mass appears relatively hypointense, with the signal intensity of the fluid within the locules reflecting differences in their hemorrhagic and proteinaceous composition.⁴⁷

Angiomyolipoma and Other Renal Manifestations of Tuberous Sclerosis

Angiomyolipoma is a benign, nonencapsulated, hamartomatous lesion of the kidney that is composed of blood vessels, smooth muscle, and fat in variable proportions.^{10, 119, 154} The tumor can arise in the cortex or the medulla. In children, angiomyolipoma is frequently multiple and bilateral, and it is almost invariably a manifestation of tuberous sclerosis. Renal cysts also occur in patients with tuberous sclerosis and can mimic familial polycystic kidney disease.^{10, 115, 119, 154} (Fig. 57–12). Occasionally, angiomyolipomas or renal cysts are detected in a child with undiagnosed tuberous sclerosis who presents with a palpable mass or hematuria. More often, other features typical of this syndrome are already known, such as adenoma sebaceum, subungual fibroma, mental retardation, seizure disorder, cardiac rhabdomyoma, and the central nervous system tubers, tumors, and heterotopias.

Demonstration of fat within a renal mass in a child is suggestive of angiomyolipoma. Rarely, however, the tumor has more vascular and muscular elements and contains little or no visible fat.^{10, 119, 154}

On ultrasound examination, angiomyolipomas are usu-

Figure 57-12. Left renal angiomyolipoma and right simple renal cyst in a 5-year-old boy with tuberous sclerosis.

A, Nonenhanced CT axial view through the kidneys just below the renal hila. Subtle, low-attenuation foci are visible in the mid right kidney anteriorly and in the mid left kidney posteriorly (arrows).

B, Contrast-enhanced CT axial view through the kidneys just below the renal hila during the corticomedullary phase. The lesions anteriorly in the right kidney and posteriorly in the left kidney are seen much more clearly than on the nonenhanced study. Both lesions again appear very low in attenuation (arrows) compared with the surrounding enhancing renal parenchyma. The small anterior lesion in the right kidney is nearly circular and is sharply defined compared with the lesion on the left, which is larger with less well defined margins.

C, Contrast-enhanced CT axial view through the kidneys just below the renal hila during the excretion phase. Delayed images show that the lesion on the right does not enhance, consistent with a simple cyst (open arrow). The lesion on the left, on the other hand, enhances very intensely, consistent with an angiomyolipoma (arrow).

ally brightly echogenic. At CT, the same areas have very low attenuation on nonenhanced scans, with an appearance similar to that of perirenal fat. Detection of the fat composition of very small angiomyolipomas can be facilitated by using single-voxel region-of-interest measurements of attenuation.⁹⁶

At MRI, the tumors are hyperintense on both T1-weighted and T2-weighted images. Because angiomyolipomas are usually very hypervascular, they enhance intensely at both CT and MRI. Larger angiomyolipomas also tend to bleed, often abruptly and profusely, resulting in areas of hemorrhage within the tumor as well as hemorrhage beneath the renal capsule and into the perirenal space; however, less vascular, smaller lesions can sometimes be difficult to distinguish from cysts. Calcification is generally absent in angiomyolipoma.

Lymphangioma and Related Disorders

Isolated renal lymphangioma is a rare, benign, cystic tumor of the kidney that can be radiographically difficult to distinguish from multilocular cystic nephroma.^{99, 125} Extensive renal lymphangiomatosis is quite rare; it produces massive, bilateral nephromegaly with residual functioning islands of renal parenchyma that appear as irregular bands separating the cystic masses. Renal lymphangiomatosis

may be isolated, but more often it occurs in association with retroperitoneal lymphangiomatosis.⁴¹ Cystic pulmonary lesions may also coexist.⁷³

Lipoblastomatosis is a benign tumor of fetal adipose tissue that occurs mainly before the age of 3 years. Lobules of immature fat are present, together with a myxoid stroma separated by vascular connective tissue septa. The fat density is easily appreciated at CT, with denser areas that represent the myxoid tissue.⁶¹

Renal Cystic Diseases

Ultrasound is used for the primary evaluation of renal cystic diseases. In general, the role of CT and MRI is limited to cases in which the sonographic appearances are confusing or when a complication such as cyst rupture, hemorrhage, or neoplasia is suspected.^{45, 77}

Isolated simple renal cysts are uncommon in children. For this reason, polycystic kidney disease should be suspected when even a single cyst is identified in an otherwise normal-appearing kidney in a child. In fact, most cystic renal lesions that are identified upon ultrasound examination in children are not cysts in the strict sense. Caliceal diverticula, hydrocalices, and even very prominent and

hypoechoic medullary pyramids are often misinterpreted as cysts.

On CT and MRI scans, simple cysts appear as homogeneous, well-defined, fluid-filled, spherical or fusiform masses with clearly defined, thin walls. In uncomplicated cysts, the fluid is of homogeneously low attenuation at CT and has low signal intensity on spin-echo and inversion recovery T1-weighted images.^{45, 46, 81, 101} On spin-echo T2-weighted images, the signal intensity of the fluid increases and the wall of the cyst and the fluid may not be distinguishable.

At MRI, hemorrhagic cysts vary widely in signal intensity. In general, the signal intensity in hemorrhagic cysts is brighter and more inhomogeneous on both T1-weighted and T2-weighted images.^{31, 46, 78, 81, 101, 109} At CT, larger clots can often be identified within cysts but differences in fluid composition and small particulate debris within the cyst fluid are more readily identified at MRI than with CT.

Calcification in the wall of the cysts is more commonly seen in adults and is rare in children. Although larger calcifications are sometimes visible as regions of signal void within the wall of the cyst at MRI, mural calcifications are better evaluated at CT or ultrasound.

Caliceal Diverticulum ("Congenital Caliceal Cyst")

A caliceal diverticulum represents a congenital malformation of the collecting system.⁷⁷ At ultrasound, caliceal diverticula appear as solitary or multiple cystic lesions within the renal parenchyma. These diverticula are usually centrally located within the kidney, adjacent to the pyramids and collecting system. Although most caliceal diverticula are small (<1 cm), occasionally they can be quite large and can vary somewhat in size and shape, depending on the degree of distention of the collecting system.

Many caliceal diverticula communicate freely with the collecting system and become opacified during either ante-

grade or retrograde urography as well as during CT. Occasionally, however, the neck of the diverticulum is stenotic, in which case the diverticulum becomes only faintly opacified or, in some cases, not at all. Detection of faint opacification of a caliceal diverticulum at CT can be assisted by comparing the attenuation within the "cyst" on delayed imaging sequences with the patient first supine and then prone.

Autosomal Recessive Polycystic Kidney Disease

Autosomal recessive polycystic disease is manifested by severe dilatation and ectasia of the collecting tubules. Because most patients with this disorder present very early in life, it is also called "infantile polycystic disease," but presentations later in childhood or adolescence are not unusual.⁷⁷

Very young patients with recessive polycystic disease have markedly enlarged kidneys. On cross-section, the dilated and ectatic collecting tubules appear as fusiform cystic structures within the enlarged medullary pyramids (Fig. 57-13). With increasingly severe involvement, the tubular ectasia extends beyond the collecting tubules in the medulla to involve the convoluted tubules. In its most severe expression, the cystic changes extend to the surface of the kidney, with innumerable cysts erupting beneath the renal capsule.

Liver disease may also occur in patients with recessive polycystic disease. Histopathologically, the spectrum of severity of the hepatic disease varies widely—from mild biliary proliferation and dilatation to biliary atresia with severe periportal fibrosis, to portal hypertension with varices and upper gastrointestinal hemorrhage. In general, patients with more severe liver involvement have less severe renal disease and usually present at a somewhat older age.⁷⁷

Recessive polycystic kidney disease is generally evaluated with ultrasonography. The kidneys are typically very

Figure 57-13. Autosomal recessive polycystic kidney disease with hepatic fibrosis in a 3-year-old girl who presented with severe hypertension. **A**, Contrast-enhanced CT axial image through the kidneys. Both kidneys are very enlarged. Dilated and ectatic collecting tubules appear as fusiform cystic structures within the very enlarged medullary pyramids. At the periphery of the kidney, the cortex is thinned and enhances inhomogeneously. **B**, Contrast-enhanced CT axial image through the liver. The intrahepatic bile ducts are diffusely dilated and ectatic.

enlarged and inhomogeneously echogenic. The echogenic appearance of the parenchyma results from the abnormally increased reflectivity of the walls of the distended and ectatic collecting tubules and distal convoluted tubules. Macrocysts, when present, are usually located peripherally, producing a hypoechoic marginal halo around the kidney and occasionally even around individual renal lobes.

Autosomal Dominant Polycystic Kidney Disease

Autosomal dominant polycystic disease occasionally presents in childhood. The cysts are usually small and few in number early in life. In neonates, the kidneys appear large and contain multiple small cysts mimicking the appearance of the recessive form of the disease.⁵⁶ As the child becomes older, the cysts increase in size and number. Eggshell mural calcification is seen only rarely in children (Fig. 57-14). Complications such as hemorrhage within a cyst can be visualized either at CT or MRI. MRI often shows striking differences in the signal intensity of the fluid in the cysts, reflecting differences in protein content of the fluid.

Multicystic Dysplastic Kidney

Atresia of the ureteral bud at or below the ureteropelvic junction results in a severely dysplastic, nonfunctioning, cystic kidney.^{57, 74, 77} The diagnosis is usually easily established on the basis of characteristic imaging findings at ultrasound and renal diuretic or cortical scintigraphy of a nonfunctioning kidney that is replaced by multiple noncommunicating cysts with no residual normal-appearing parenchyma. At CT and MRI, the kidney is shown to be entirely replaced by multiple cysts of different sizes that are separated by a small amount of nonfunctioning, dysplastic parenchyma.

In the hydronephrotic variant of multicystic dysplasia, the kidney is nonfunctioning and contains one or more smaller peripheral cysts, with a large central cyst representing the dilated, dysmorphic collecting system.⁵⁷ In the

segmental multicystic dysplastic kidney, the anomaly affects only one moiety of a partially or completely duplicated collecting system.⁸⁵ Bilateral multicystic renal dysplasia is incompatible with extrauterine life and is accompanied by severe oligohydramnios, pulmonary hypoplasia, and the other features of Potter's syndrome.

In most patients with a multicystic dysplastic kidney, the fluid within the cysts is gradually absorbed and the kidney progressively decreases in size until it is no longer identifiable at ultrasound. This process of involution of a multicystic dysplastic kidney results in an appearance that is indistinguishable from unilateral renal agenesis. Because the dysplastic renal remnant has no function, it is not identifiable at renal scintigraphy. In patients who have severe hypertension or other signs or symptoms suggestive of an occult, dysplastic kidney, MRI has been used to identify the tiny offending dysplastic remnant.

Renal Trauma

CT is commonly used to evaluate patients with suspected renal trauma. It provides excellent anatomic and functional information that correlates very closely with surgical findings. It is superior to either urography or ultrasonography in patients who have traumatic renal injuries. In addition, with CT, the entire abdomen and pelvis can be rapidly surveyed, permitting immediate diagnosis of associated injuries to other viscera.^{25, 55, 89, 98, 136}

Renal injuries range from isolated parenchymal contusions with no associated subcapsular or perirenal hemorrhage (grade I) to superficial parenchymal lacerations that do not involve the collecting system (grade II), to deeper parenchymal lacerations that are associated with urinary extravasation (grade III), to extensive disruption and fragmentation of the kidney (grade IV) (Table 57-2). Grades I and II injuries account for more than half of all injuries in children.^{89, 139} The possibility of a preexisting renal abnormality should always be considered. Kidneys that are abnormally large, hydronephrotic, or ectopic, or that contain masses or cysts, are more prone to injury^{67, 130} (Fig. 57-15).

Function is commonly decreased or absent in the area of the injury as a result of venous thrombosis and vascular compression by adjacent edematous parenchyma or clot. With more minor injuries, function often returns with healing; however, in patients with extensive parenchymal fractures, infarction of completely devascularized renal fragments is not associated with recovery of function. Disruption or thrombotic occlusion of polar arterial

Figure 57-14. Autosomal dominant polycystic kidney disease in an 8-year-old girl. Contrast-enhanced CT axial image through the kidneys. Innumerable cysts are present throughout both kidneys, surrounded by normally enhancing renal parenchyma.

Table 57-2. CT Grading of Renal Trauma

Grade I	Small parenchymal injury No subcapsular or perirenal fluid Uninjured anomaly
Grade II	Incomplete renal laceration Subcapsular or small amount of perirenal fluid
Grade III	Extensive laceration or fracture
Grade IV	Multiple fragments (shattered)
Grade V	Vascular injury

From Karp MP, Jewett TC, Kuhn JP, et al: The impact of computed tomography scanning on the child with renal trauma. *J Pediatr Surg* 21:617-623, 1986.

Figure 57-15. Rupture of the right renal collecting system and right perinephric urinoma in an 11-year-old boy with preexisting severe ureteropelvic junction obstruction. The patient presented with gross hematuria and abdominal pain after a skiing accident.

A, Contrast-enhanced CT axial image through the kidneys performed several hours after the injury. There is moderate right hydronephrosis with severe, diffuse, cortical thinning consistent with long-standing obstructive uropathy. A large right perinephric fluid collection is also present.

B, Contrast-enhanced CT axial image through the kidneys 6 weeks after the injury. The right hydronephrosis has considerably increased and the collecting system appears more tense. The cortex is diffusely and severely thinned; it appears as enhancing crescents surrounding the dilated calices that are filled with nonopacified urine. The perinephric fluid collection has resolved.

branches can also lead to segmental parenchymal infarcts.^{136, 139}

Subcapsular and perirenal hemorrhages often accompany superficial and deeper parenchymal lacerations.^{89, 139} Subcapsular fluid collections closely conform to the renal contour and are separated from Gerota's fascia by the perirenal fat. On the other hand, perirenal blood extends to Gerota's fascia. On nonenhanced images obtained early after the injury, subcapsular and perirenal blood appears higher in attenuation than the adjacent renal parenchyma. After contrast material is given, the renal parenchyma enhances and the adjacent, nonenhancing clot appears relatively lower in attenuation. As the clot matures and liquefies, its attenuation gradually decreases. Urinomas resulting from disruption of the walls of the collecting system or proximal ureter appear as masses of fluid attenuation. If the leakage is still active during the study, the mass will contain opacified urine and the site of the extravasation from the collecting system can occasionally be directly identified (Fig. 57-16).

An injury to the renal vascular pedicle should be suspected when there is complete loss of flow and function in the kidney. This is a critical point, because renal pedicle injury is one of the few absolute indications for emergent surgical intervention. Collateral flow through capsular vessels frequently results in a rim of enhancement at the periphery of the kidney.^{70, 120} Severe renal vascular compromise can result from subendothelial hemorrhage or dissection within the wall of the renal artery, from direct laceration of the vessel, or from extrinsic compression of the renal vascular pedicle by adjacent hematoma in the perirenal space.

Surgical intervention is usually limited to those patients who are hemodynamically unstable and those who are thought to have injuries to the renal vascular pedicle.^{6, 89}

Early CT permits rapid and accurate diagnosis of the nature and severity of the child's injuries. Although ultrasound generally has no role in the acute investigation of the child with suspected blunt renal injury, it is ideally suited for follow-up of abnormalities that have been previously demonstrated by CT. With conservative management, the rate of renal salvage is high. Hypertension is the most common long-term clinical complication.^{1, 6, 110}

Adrenal Glands

Although the adrenal glands are generally easily visualized by ultrasonography in neonates and infants, the reliability of this modality diminishes with age and CT and MRI are more sensitive in diagnosing and characterizing adrenal disease in older children. Nonetheless, ultrasound is still used as the primary screening modality in most forms of adrenal disease because it does not expose the patient to ionizing radiation and it is widely available; however, when adrenal pathology is strongly suspected clinically, either MRI or CT or both should be performed, even when ultrasonographic findings are negative.

Normal Anatomy

At CT, the adrenal glands appear as triangular or crescentic soft tissue structures draped over the upper poles of the kidneys immediately anterolateral to the crura of the diaphragm. The two limbs of each adrenal gland appear as thin strands that join superiorly. At MRI, the normal adrenal glands appear on T1-weighted images as triangular or crescentic suprarenal structures of medium signal intensity, with the two limbs of each gland outlined by the high-

Figure 57-16. Left renal fracture with laceration of the collecting system and lower pole infarction in a 5-year-old girl who was run over by a bulldozer. *A*, Contrast-enhanced CT axial image through the lower poles of the kidneys several hours after the injury. The lower pole of the left kidney enhances very poorly, especially the lateral half. Perinephric extravasation of contrast material secondary to laceration of the collecting system has resulted in a large, opacified perinephric fluid collection surrounding the lower pole of the left kidney. The lower pole of the right kidney appears normal. *B*, Contrast-enhanced CT axial image through the lower poles of the kidneys 2 months later. The contour of the lower pole of the left kidney appears somewhat irregular. The medial portion of the lower pole still enhances poorly. The perinephric urinoma has resolved.

signal-intensity perirenal fat.^{27, 81} On T2-weighted images, the adrenals have slightly greater signal intensity but still show less intensity than the surrounding fat.

The normal triangular, “arrowhead” configuration of the adrenal gland results from elevation of the two adrenal limbs by the upper pole of the subjacent kidney. For this reason, when a kidney is absent or ectopic, the ipsilateral adrenal gland assumes an elongated, linear, or discoid configuration and occupies more of the renal fossa than normal.¹⁴¹ On axial images, the elongation of the adrenal gland in this situation is often difficult to recognize; on coronal MRI images, the discoid adrenal gland appears as an elongated linear structure and should not be mistaken for a small hypoplastic or dysplastic kidney.

Adrenal Hemorrhage

Adrenal hemorrhage occurs in fetuses and neonates secondary to a variety of perinatal insults, including hypoxemia, metabolic acidosis, septicemia, renal vein thrombosis, coagulation disorders, and birth trauma.^{27, 53, 113, 161} Anemia and jaundice are common. Larger hemorrhages may appear with hypovolemic shock, profound anemia, and a palpable mass. In some patients, the hemorrhage is asymptomatic and is discovered incidentally during abdominal or renal sonography performed for an unrelated reason.

Ultrasonography is the modality of choice both for the initial evaluation and for follow-up of neonates thought to be having adrenal hemorrhage. Imaging with other modalities, such as CT or MRI, is unnecessary except when there is concern that the hemorrhage might be masking an underlying adrenal neoplasm, such as neuroblastoma. Even in this case, serial sonography and a “tincture of time”¹⁵⁷ are usually the optimal approach because adrenal hemorrhage will liquefy and contract in size over several weeks. Given the generally excellent prognosis in neonatal neuroblastoma, aggressive multimodality imaging is not war-

ranted unless a subsequent sonogram shows an enlarging mass or evidence of regional nodal or liver metastases.

Chunky or speckled calcification within the mass also suggests neuroblastoma. Calcification is not present early in the course of adrenal hemorrhage, although the hematoma can calcify later, usually beginning at the periphery. More often, neither MRI nor CT can clarify the situation, because both yield findings of a complex, hemorrhagic adrenal mass.^{27, 53, 113, 161} Acutely, adrenal hemorrhage has low signal intensity on T1-weighted images. Subacute hemorrhage has very bright signal on both T1-weighted and T2-weighted images.

Adrenal Tumors

Neuroblastoma

Neuroblastoma is the most common primary extracranial solid tumor in childhood.^{26, 27, 44, 113} It can occur anywhere along the sympathetic chain from the neck to the pelvis; 75% are in the abdomen, and two thirds of these (50% of the total) are in the adrenal gland. Twenty percent of neuroblastomas occur in the chest and neck. Most children with neuroblastoma are between 1 and 5 years of age.

Symptoms are related to the primary tumor and to metastases, which are present at initial diagnosis in more than half of patients. A mass is frequently palpable. Pain is common, both from the primary tumor and from metastases, and the child appears ill and irritable. Large paraspinal tumors can lead to paraplegia and urinary and fecal retention or incontinence secondary to involvement of the spinal cord and lumbosacral nerve roots. The most common sites of metastases are regional and distant lymph nodes, cortical bone, bone marrow, skin, and liver. Lung metastases are rare. In patients with extensive marrow involvement, profound anemia and thrombocytopenia can mimic primary reticuloendothelial disease.

Symptoms related to secretion of neurotransmitters are

Figure 57-17. Stage IV-S right adrenal neuroblastoma with liver metastases in a 4-month-old boy who presented with multiple nodular skin metastases on physical examination. *A*, Contrast-enhanced CT axial image through the upper abdomen. A 5-cm, solid, right suprarenal mass exhibits a somewhat inhomogeneous attenuation and indents the anterior surface of the upper pole of the right kidney. Scattered mottled calcifications are visible within the mass. *B*, Contrast-enhanced CT axial image through the liver. Multiple low-attenuation, nonenhancing lesions are visible throughout the liver, consistent with metastases.

common, and hypertension is present in 5%. Opsomyoclonus is a rare clinical syndrome that occurs in 2% of children with neuroblastoma. Opsomyoclonus is characterized by chaotic, disconjugate eye movement. Myoclonic jerks and cerebellar ataxia are also frequently present.^{48, 54} Half the children with opsomyoclonus have neuroblastoma. Because these tumors are often small and may not produce catecholamines, CT or MRI screening is performed to identify nonpalpable neuroblastomas in this group of patients. The neurologic signs and symptoms often improve with removal of the tumor.

At CT, abdominal neuroblastoma appears as an irregular, lobulated, suprarenal or paraspinal mass^{105, 152} (Fig. 57-17). Areas of hemorrhage, necrosis, and cyst formation are common. Chunky or speckled calcification is visible within the mass at CT in 80% of patients. Unlike Wilms' tumor, which typically has a well-defined pseudocapsule, neuroblastoma frequently invades adjacent structures and encases the aorta and its branches early in the course of the disease. Neuroblastoma frequently spreads to retroperitoneal lymph nodes, and retrocaval lymphadenopathy is specific for neuroblastoma.

Encasement of the aorta and its main branches is more important in guiding management and determining prognosis than the conventional staging system, which uses the midline as a landmark between stage II and stage III disease (Table 57-3). Although neuroblastomas that cross the midline but do not encase major vessels technically represent stage III disease, they are usually still surgically resectable even when they are very large or involve regional lymph nodes.¹⁶

Paraspinal neuroblastomas that extend directly through the neural foramina to involve the spinal cord and roots are best evaluated with MRI. The appearance of a "dumbbell" mass centered at one or more foramina is characteristic of paraspinal neuroblastoma.

On T1-weighted images, the signal intensity of neuroblastoma is similar to that of the renal medulla and slightly lower than that of liver or renal cortex. The signal intensity

of the mass increases on T2-weighted images and appears similar to that of kidney.⁴⁴ Marrow involvement is best demonstrated on T1-weighted images, with the normally high-signal-intensity marrow fat replaced by lower-signal-intensity tumor. On T2-weighted images, the tumor is more similar in signal intensity to marrow and less easily identified. Calcifications are not usually visible on MRI scans unless they are large, in which case they appear as very-low-signal areas within the mass on both T1-weighted and T2-weighted images. When neuroblastoma invades the adjacent kidney, it can mimic a primary intrarenal mass,^{105, 134} but tumor calcification, retroperitoneal lymphadenopathy, and encasement of the aorta and inferior vena cava are far more likely in neuroblastoma than in Wilms' tumor.

After treatment, CT scanning offers the most sensitive method of detecting tumor recurrence.¹⁵³ Both CT and MRI scanning can identify tumor recurrence in the retroperito-

Table 57-3. Staging of Neuroblastoma

Stage I	Tumor confined to organ or structure of origin and completely resected
Stage II	Tumor extending in continuity beyond the organ or structure of origin, but not crossing the midline. Regional lymph nodes on the ipsilateral side may be involved.*
Stage III	Tumors extending in continuity beyond the midline. Regional nodes bilaterally may be involved.
Stage IV	Remote disease involving skeleton, parenchymatous organs, soft tissues, or distant lymph node groups (see stage IV-S).
Stage IV-S	Disease that would otherwise be stage I or II but is remote and confined to one or more of the following sites: liver, skin, or bone marrow, without radiographic evidence of cortical bone metastases on complete skeletal survey.

*All "dumbbell" tumors are classified as stage II unless the abdominal or thoracic portion crosses the midline.

From Stark DD, Brasch RC, Moss AA, et al: Recurrent neuroblastoma: The role of CT and alternative imaging tests. *Radiology* 148:101-105, 1983.

neum, liver, cranium, mediastinum, lymph nodes, and skeleton.

Adrenal Cortical Tumors

Adrenal cortical tumors are quite rare during childhood but tend to be highly malignant and locally invasive.^{39, 92, 166} Carcinoma is three times as common as adenoma in children, compared with the much higher proportion of adenomas in adults.⁶⁴ The tumors are usually unilateral and are hormonally active in most cases. Excess androgens produce virilization in girls and pseudoprecocious puberty in boys. Cushing's syndrome, feminization, and hyperaldosteronism are less common findings.

At CT, adrenal cortical tumors are seen as an inhomogeneous, complex solid mass with internal areas of necrosis and hemorrhage.³⁹ Calcification is occasionally present. Tumors larger than 5 cm in diameter are more likely to be carcinomas. Carcinomas also tend to have more irregular margins, and they demonstrate a somewhat higher signal intensity at MRI than adenomas do⁶⁴; however, an adenoma cannot be reliably differentiated from carcinoma at either CT or MRI^{27, 64, 113} except when local invasion or distant metastases are identified. Carcinomas commonly extend into the adrenal vein and inferior vena cava (Fig. 57–18). CT of the lungs should be performed in all cases to exclude metastases.

Pheochromocytoma and Paraganglioma

Pheochromocytomas are rare in childhood. They can occur wherever chromaffin tissue is found.^{14, 46, 50, 52, 113} Eighty percent arise in the adrenal gland. Extra-adrenal tumors, referred to as paragangliomas, can occur in a variety of locations, including the organ of Zuckerkandl, sympathetic ganglia, nerve plexuses, and nerves.

Patients with von Hippel–Lindau disease, multiple endocrine neoplasia syndrome, and familial pheochromocytoma are at increased risk for development of pheochromocytoma;

however, most occur sporadically. Multiple tumors are present in one third of patients and are more common in those patients who have one of these syndromes. Fewer than 10% of tumors are malignant. The most common sites of metastases are bone, liver, lymph nodes, and lung, and rarely, the central nervous system.

Symptoms are secondary to secretion by the tumor of epinephrine or norepinephrine or both, and occasionally dopamine. Seventy percent to 80% of patients have hypertension, which is often severe. Less common manifestations include headache, sweating, palpitations, anxiety, tremor, nausea, vomiting, abdominal and chest pain, and visual disturbances. The clinical diagnosis of pheochromocytoma can usually be confirmed in patients who have sustained hypertension by documenting elevated levels of catecholamines and their metabolites in plasma and 24-hour urine collections.¹¹³ Biochemical diagnosis is more difficult in patients who have only episodic symptoms or who are asymptomatic.

Once the clinical diagnosis has been established, CT or MRI can be used to localize the tumor for surgical resection. At MRI, pheochromocytomas have slightly lower signal intensity than liver on T1-weighted sequences and very high signal intensity on T2-weighted images.^{14, 67} In some cases, the very bright signal intensity of the tumor on T2-weighted images can mimic that of a cyst.³² After gadolinium administration, tumor enhancement is marked even during the early phase.^{14, 82, 83, 95} Smaller tumors are typically more homogeneous than larger masses, which often contain areas of cystic degeneration and necrosis. CT and MRI are equally sensitive in detecting adrenal pheochromocytomas.⁵² Direct coronal imaging with MRI permits rapid screening of large sections of the body and is somewhat more sensitive than CT for identifying extra-adrenal tumors. Neither modality can distinguish between benign and malignant pheochromocytomas unless metastases are visible.³²

Figure 57–18. Right adrenal cortical carcinoma with intracaval extension in a 9-year-old girl with Cushing's syndrome. **A**, Contrast-enhanced CT axial image through the upper abdomen shows a 3-cm, solid, right adrenal mass of inhomogeneous attenuation. The mass has slightly irregular margins with thin strands extending into the pararenal fat posteriorly. The inferior vena cava enhances homogeneously at this level. **B**, Contrast-enhanced CT axial image through the upper abdomen. The right adrenal mass is difficult to separate from the overlying liver. Thin strands are again visible extending from the mass into the pararenal fat adjacent to the right diaphragmatic crux. In addition, there is an irregular intraluminal filling defect within the inferior vena cava, consistent with intravascular extension of the adrenal tumor.

Gastrointestinal Tract, Peritoneal Cavity, and Mesentery

Carlos J. Sivit

Gastrointestinal Tract

Computed tomography (CT) is commonly used in the assessment of children with suspected gastrointestinal (GI) tract pathology. Recent advances in CT scanning have substantially altered the imaging evaluation of many common GI tract conditions, many of which present a diagnostic challenge to caregivers. An accurate diagnosis is essential for triage, or separation of children who require surgery from those who can be managed nonoperatively.

Infectious and Inflammatory Conditions

Acute Appendicitis

Acute appendicitis is the most common condition requiring emergency abdominal surgery in childhood.¹⁹ It is typically seen in older children and adolescents. Although the diagnosis has traditionally been based on clinical criteria, the clinical diagnosis is not always straightforward, and approximately one third of patients with the disease have an uncertain preoperative diagnosis.^{24, 44} This in turn may result in a delay in surgery with resultant increased morbidity, including perforation, abscess formation, and peritonitis.

CT is becoming the principal imaging modality for the evaluation of suspected acute appendicitis in childhood. It is a highly sensitive and specific modality for such diagnosis. CT has been shown to have a higher diagnostic accuracy than graded-compression sonography for such diagnosis.^{14, 22} A variety of techniques have been used in the performance of appendiceal CT, including:

1. Full abdominopelvic scanning after intravenous and oral administration of contrast material.³
2. Imaging limited to the lower abdomen and upper pelvis without any contrast material.^{23, 27}
3. Imaging of the lower abdomen and upper pelvis with thin (4-mm) collimation and only rectal contrast material.^{14, 35}

The use of rectal contrast in conjunction with thin collimation has yielded the highest reported diagnostic accuracy.^{14, 35} Rectal contrast in children with suspected acute appendicitis is typically well tolerated. A 3% diatrizoate solution is administered intracolonicly through a rectal catheter. The administered fluid volume ranges from 500 mL in small children to 1000 mL in teenagers.

At CT, signs of acute appendicitis include a distended (>7 mm) and unopacified appendix (Fig. 58-1), appendiceal wall thickening and enhancement (see Fig. 58-1), an appendicolith (Fig. 58-2), cecal apical thickening (see Fig. 58-1), deformity of the cecal tip (arrowhead sign) (Fig. 58-3), pericecal fat stranding (see Fig. 58-1), mesenteric lymphadenopathy, and peritoneal fluid. Secondary changes, including cecal apical changes and stranding of pericecal fat, can be quite useful when the appendiceal diameter measurement is borderline. After rupture, the appendix is usually not visualized. Findings at CT following ruptured appendicitis include the presence of abdominal or pelvic phlegmon or abscess (Fig. 58-4).

Inflammatory Bowel Disease

Inflammatory bowel disease is commonly encountered in older children and adolescents. The principal conditions are Crohn's disease and ulcerative colitis, which are both idiopathic inflammatory conditions.

Crohn's disease, the most common chronic inflammatory GI tract condition in childhood (and thus seen more frequently than ulcerative colitis), most often affects the terminal ileum (Fig. 58-5) but can involve any region of the GI tract. It is characterized by skip areas of involvement, whereas the lesions in ulcerative colitis tend to be continuous.

Crohn's disease is a transmural process associated with severe complications, including ulceration, strictures, fistula formation, and perforation with abscess formation. Ulcerative colitis is characterized by superficial inflammatory changes typically confined to the mucosa and submucosa. Therefore, the serious complications seen in Crohn's disease are uncommon in ulcerative colitis, although an

Figure 58-1. Acute appendicitis. A, CT scan through the lower abdomen in a patient with appendicitis demonstrates an enlarged, thick-walled appendix with wall enhancement and an associated infiltration of surrounding fat. B, CT scan through the upper pelvis in the same patient demonstrates cecal apical thickening.

association exists between ulcerative colitis and the later development of carcinoma of the colon.

CT is frequently used in the evaluation of children with inflammatory bowel disease, although many of the findings are nonspecific and may also be seen with infectious, ischemic, or radiation-induced enteritis or colitis; vasculitis; or graft-versus-host disease. Predominant involvement of the distal small bowel and right colon is more common in Crohn's disease (see Fig. 58-5), whereas involvement of the rectum and sigmoid colon is more common in ulcerative colitis (Fig. 58-6).

One rather specific CT finding in patients with Crohn's disease is the presence of fibrofatty proliferation of the

mesentery surrounding the involved colon (Fig. 58-7).³² Additionally, bowel wall thickening tends to be more pronounced in Crohn's disease than in ulcerative colitis.¹⁸ Extensive bowel fibrosis is often present in advanced cases of Crohn's disease, resulting in marked luminal narrowing. CT plays an important role in the evaluation of children thought to have complications such as bowel obstruction, bowel perforation, and abscess, phlegmon, and fistula for-

Figure 58-2. Appendicolith. CT scan through the upper pelvis of a patient with appendicitis shows an enlarged appendix containing an appendicolith.

Figure 58-3. Acute appendicitis. CT scan through the lower abdomen in a child with appendicitis demonstrates the "arrow-head sign" consisting of a triangle-shaped contrast collection between the thickened cecal apical walls.

Figure 58-4. Ruptured appendix. CT scan through the lower abdomen in a patient with a ruptured appendix demonstrates multiple rounded, low-attenuation interloop collections representing multiple abscesses.

mation (Fig. 58-8).^{15, 18, 32} Bowel perforation and abscess formation occur more commonly in Crohn's disease than in ulcerative colitis.

Pseudomembranous Colitis

Pseudomembranous colitis is an iatrogenic disease that is almost exclusively related to an alteration of colonic microflora by antibiotic that facilitates colonization by *Clostridium difficile*.⁸ An occasional case is associated with *Staphylococcus* infection. The spectrum of severity is wide, and the disease is occasionally fatal. The diagnosis is established by endoscopic demonstration of characteristic yellow plaques (pseudomembranes) on colonic mucosa, or by laboratory documentation of the *C. difficile* enterotoxin. The condition is managed conservatively, with cessation of the implicated antibiotic, institution of appropriate antibiotic therapy, and maintenance of fluid and electrolyte balance.

Figure 58-6. Ulcerative colitis. CT scan through the pelvis in a patient with ulcerative colitis demonstrates mild thickening of the sigmoid colon.

CT is usually obtained in patients with suspected pseudomembranous colitis to assess for possible complications, including bowel obstruction and perforation with abscess formation. CT findings associated with pseudomembranous colitis are nonspecific and may be seen with any severe infectious or ischemic colitis. For example, contrast material trapped between thickened haustral folds, referred to as the accordion sign (Fig. 58-9),^{12, 26, 36} may be noted in a variety of other infectious and inflammatory conditions that involve the colon.²⁶ The thickened colonic wall in pseudomembranous colitis typically has a low attenuation value (Fig. 58-10). Colonic involvement may be diffuse or segmental^{7, 26, 36}; the diffuse form is more common. Because the appearance of pseudomembranous colitis is normal in nearly 40% of patients at CT,⁷ this is not a sensitive method of establishing the diagnosis.

Neutropenic Typhlitis

Neutropenic typhlitis is a necrotizing enteropathy of the right colon that develops in the setting of neutropenia. It probably begins secondary to a cytotoxic drug-induced

Figure 58-5. Crohn's disease. A, CT scan through the lower abdomen in a patient with Crohn's disease demonstrates thickening of the distal ileum. B, CT scan in the same patient 2 cm below A shows marked thickening of the distal ileum.

Figure 58-7. Crohn's disease. A, CT scan through the midpelvis in a patient with Crohn's disease demonstrates marked fibrofatty mesenteric proliferation. B, CT scan in same patient 2 cm below A demonstrates thickening of the sigmoid colon.

Figure 58-8. Crohn's disease complicated by perforation and phlegmon formation. CT scan through the upper pelvis in a patient with Crohn's disease demonstrates a phlegmon in the right iliac fossa.

Figure 58-9. Pseudomembranous colitis. CT scan through the midabdomen in a patient with pseudomembranous colitis shows contrast material trapped between thickened haustral folds, a finding that has been labeled the "accordion sign."

Figure 58-10. Pseudomembranous colitis. CT scan through the lower abdomen in a patient with pseudomembranous colitis demonstrates diffuse colonic wall thickening. The wall has a homogeneous, low-attenuation appearance.

ileus, and it may become complicated by secondary bacterial invasion. Mucosal ulceration is seen early, and it can progress to mucosal and submucosal necrosis accompanied by intramural edema and hemorrhage. The condition is usually restricted to the cecum, ascending colon, appendix, and terminal ileum. Neutropenic typhlitis occurs most commonly in children with leukemia.⁵¹ The spectrum of clinical disease is wide, and perforation is a rare complication.

CT is useful in the assessment of children believed to have neutropenic typhlitis, particularly if complications such as bowel obstruction and perforation are suspected. The examination should be performed following a delay of at least 2 hours after the administration of oral contrast material to allow the contrast to reach the colon. Rectal contrast is contraindicated in these patients, who are at increased risk for perforation. CT findings in patients with neutropenic typhlitis include colonic, distal ileal, and appendiceal wall thickening (Fig. 58-11).^{6, 10} The ascending and transverse colon may also be affected. Associated stranding of pericecal fat is often visualized, and pneumatosis intestinalis is occasionally involved. Follow-up ex-

Figure 58-11. Neutropenic typhlitis. CT scan through the lower abdomen in a patient with leukemia and neutropenic typhlitis demonstrates cecal thickening.

aminations with CT typically show decreasing bowel wall diameters corresponding to clinical improvement.

Graft-versus-Host Disease

Graft-versus-host disease is specific to allogeneic bone marrow transplantation. It is initiated by immunocompetent donor T cells that react with the host cells. The disease is considered acute if it occurs in the first 100 days following transplantation and chronic if it develops after 100 days. The disease is characterized by crypt cell necrosis and diffuse mucosal destruction throughout the small and large intestines. Clinical grading of the acute form is based on the degree of damage to the skin, GI tract, and liver.

The CT appearance of graft-versus-host disease is similar in the acute and chronic forms and includes segmental or diffuse bowel wall thickening; fluid-filled, dilated bowel loops; abnormally intense bowel wall enhancement; and infiltration of mesenteric fat.^{6, 10} Bowel wall thickening may involve the small or large bowel, and it is typically less severe than that observed in neutropenic typhlitis or pseudomembranous colitis. Stricture formation with subsequent small-bowel obstruction has been reported as an uncommon sequela (Fig. 58-12).⁶

Ischemic Colitis

Ischemic colitis in children is rare. It is typically associated with multisystem disease, colonic obstruction, or vasculitis. It encompasses a wide spectrum of severity ranging from mild reversible disease to bowel infarction and perforation. Ischemic colitis is usually characterized by mucosal necrosis and ulcerations, submucosal edema, and hemorrhage that may progress to infarction.^{1, 4}

Colonic involvement may be segmental or diffuse. The segmental form, which is more common,¹ often involves "watershed areas" at sites between different vascular supplies. These include the ascending colon near the splenic flexure (at the junction between the superior and inferior mesenteric arterial blood supplies) and the rectosigmoid junction (between the inferior mesenteric and hypogastric arterial blood supplies).¹ Thickened bowel wall associated

Figure 58-12. Graft-versus-host disease complicated by small bowel obstruction. CT scan through the midabdomen in a patient with prior graft-versus-host disease demonstrates diffuse small bowel dilatation indicative of a small-bowel obstruction. At surgery, a stricture was identified.

with bowel ischemia may have a variable appearance at CT, ranging from homogeneous to heterogeneous attenuation (Fig. 58-13). Intramural air (pneumatosis intestinalis) is also occasionally associated.

Neoplasms

Lymphoma is the primary neoplasm involving the GI tract in children and adolescents. Rarely, carcinoma of the colon may be noted in adolescents. Adenocarcinoma is the most common histologic type of colon carcinoma.

Lymphoma

The GI tract is the most commonly involved extranodal site of lymphoma. GI tract involvement is seen more frequently in non-Hodgkin's than in Hodgkin's lymphoma.⁵² The mesentery is typically also involved.

CT findings of GI tract lymphoma include segmental or multifocal thickening of the stomach and of the small or large bowel (Fig. 58-14).^{13, 38, 52} The stomach is the most frequent site, followed by the small intestine.¹³ The bowel wall thickening may become quite bulky and masslike; however, because associated luminal narrowing is uncommon, bowel obstruction is rare unless an intussusception occurs as a complication (Fig. 58-15).⁵² Ulceration may occur, resulting in perforation and abscess formation. Associated mesenteric lymph node enlargement and mesenteric masses are commonly noted.¹³

Colon Carcinoma

Carcinoma of the colon is rarely noted in adolescents with familial polyposis syndromes and in children who have undergone a urinary diversion procedure in which the ureters are diverted into the sigmoid colon. Even when associated with those conditions, however, carcinoma of the colon is more likely seen in adulthood; fewer than 1% of cases are seen in patients under 25 years of age. The

Figure 58-13. Ischemic colitis. *A*, CT scan through the midabdomen demonstrates bowel wall thickening in the transverse colon. *B*, CT scan in same patient 3 cm below *A* demonstrates bowel wall thickening involving the ascending colon. The thickened colonic wall has a diffuse, low-attenuation appearance. The patient was noted to have ischemic colitis with perforation at surgery.

CT appearance of colonic carcinoma at CT includes an irregular mass originating in the wall of the large bowel (Fig. 58-16), usually with associated luminal narrowing. Associated mesenteric and retroperitoneal lymphadenopathies are common.

Trauma

Bowel Injury

Most bowel injuries in children result from motor vehicle crashes in which they were wearing lap belts. These

children demonstrate lap-belt ecchymoses, which are linear and located in the lower abdomen or flank.⁴⁹ Bowel injury can be a partial-thickness tear, resulting in an intramural hematoma, or a full-thickness tear, resulting in bowel rupture.

The most common location of an intramural bowel hematoma is the duodenum.^{54, 57} Intramural hematomas result in eccentric bowel wall thickening at CT. Large hematomas appear dumbbell-shaped at CT (Fig. 58-17) and may result in a proximal small-bowel obstruction. These injuries can typically be managed nonoperatively, although gastric decompression may be required for a week or more.

Bowel rupture occurs most commonly in the mid to distal jejunum.⁴³ The most common findings at CT include moderate to large “unexplained” peritoneal fluid collections (peritoneal fluid in the absence of solid viscus injury or pelvic fracture) and intense bowel wall enhancement (Fig. 58-18).^{16, 29, 43, 54, 57} Extraluminal air is noted in only approximately one third of patients.⁴³ Additional CT find-

Figure 58-14. Non-Hodgkin's lymphoma involving the distal small bowel. CT scan through the lower abdomen in a patient with non-Hodgkin's lymphoma demonstrates bowel wall thickening involving the distal ileum. Note the associated mesenteric masses.

Figure 58-15. Small bowel intussusception. CT scan through the upper abdomen in a patient with lymphoma shows a small bowel intussusception.

Figure 58-16. Adenocarcinoma of the colon. CT scan through the lower abdomen of an adolescent patient demonstrates irregular thickening of the ascending colon with luminal narrowing and associated mesenteric lymphadenopathy. At surgery, adenocarcinoma of the colon was noted.

ings associated with bowel rupture include bowel dilatation, bowel wall thickening, and, rarely, extravasation of oral contrast.^{16, 29, 43, 54, 57}

Hypoperfusion Complex

A characteristic hypoperfusion complex associated with hypovolemic shock may be seen at CT in severely injured young children.^{47, 55} This topic is included here because many of the CT findings associated with the complex involve the GI tract. Most children with the hypoperfusion complex have arterial hypotension on admission, indicating uncompensated shock.⁴⁷ The hypoperfusion may be transiently corrected, and the children may be thought to be hemodynamically stable enough to undergo CT; however, rapid hemodynamic decompensation may develop subsequently.

Figure 58-17. Intramural duodenal hematoma. CT scan through the upper abdomen in a patient following blunt abdominal trauma demonstrates a large, dumbbell-shaped duodenal hematoma.

CT findings in all children with the hypoperfusion complex include diffuse intestinal dilatation with fluid; abnormally intense contrast enhancement of bowel wall, mesentery, kidneys, aorta, and inferior vena cava; and diminished caliber of the aorta and inferior vena cava (Fig. 58-19).^{47, 55} Variable findings associated with systemic hypoperfusion include intense contrast enhancement of the adrenal glands, decreased pancreatic and splenic enhancement, periportal low-attenuation zones, and peritoneal and retroperitoneal fluid.

The hypoperfusion complex, a strong predictor of a poor outcome, is associated with a high mortality rate.^{47, 55} There is great overlap of observed findings at CT in the hypoperfusion complex and in bowel rupture.⁴³ Both conditions demonstrate intense bowel wall enhancement, bowel dilatation, bowel wall thickening, and moderate to large amounts of “unexplained” peritoneal fluid.

Peritoneal Cavity

Although primary abnormalities of the peritoneal cavity and its specialized folds (the mesentery and omentum) are rare, these sites are often involved in infectious, neoplastic, and traumatic conditions that originate at other sites in the abdomen or pelvis. Therefore, knowledge of the spectrum of disease processes that involve these sites is essential to optimize the value of CT in the evaluation of a variety of complex abdominal and pelvic conditions.

The peritoneum is composed of a serous membrane extending from the abdomen to the pelvis. It consists of two portions: a parietal and a visceral peritoneum. The term *parietal peritoneum* is used to describe the portions that cover the abdominal wall, and the term *visceral peritoneum* refers to the portions that cover viscera. The peritoneal cavity lies between these two layers. In nonpathologic states, it is largely a potential space containing minimal fluid.

The peritoneal cavity is divided into various spaces by ligaments, which are folds of peritoneum. The mesentery and omenta are specialized folds of peritoneum. The mesentery is a broad, fan-shaped fold composed of a double layer of serous membrane. It encloses the jejunum, ileum, and transverse and sigmoid colons. The mesentery also connects those segments of bowel to the posterior abdominal wall.

The major divisions of the peritoneal cavity are made by the transverse mesocolon, which separates the supramesocolic and inframesocolic compartments. The supramesocolic compartment is further divided into perihepatic and perisplenic spaces. Morison's pouch is a posterior extension of the perihepatic space. It is the most dependent recess in the upper abdomen. The inframesocolic compartment is subdivided into the right and left paracolic spaces located lateral to the ascending and descending colons, the lateral paravesical recesses, and the midline pouch of Douglas. The pouch of Douglas, which is located posterior to the bladder and anterior to the rectosigmoid colon, is the most dependent portion of this compartment and of the greater peritoneal cavity.

Figure 58-18. Jejunal rupture. *A*, CT scan through the upper abdomen of a patient injured in a motor vehicle crash shows free peritoneal fluid in Morison's pouch. *B*, CT scan through the pelvis in the same patient shows a large amount of peritoneal fluid. No solid viscus injury was identified. At surgery, a jejunal rupture was noted.

Infectious and Inflammatory Conditions

Peritoneal Abscess

Peritoneal cavity infection may be localized (peritoneal abscess) or generalized (peritonitis). The spread of an abscess within the peritoneal cavity has been well described by Meyers.²⁸ Factors that affect such spread are the primary site of infection, gravity, mesenteric partitions, peritoneal recesses, and pressure gradients.²⁸ In the inframesocolic compartment, the site of initial accumulation is the pouch of Douglas, which is the most dependent site (Fig. 58-20). From the pouch of Douglas, the infectious process preferentially ascends into the right paracolic recess and drains into Morison's pouch.

The most common source of a peritoneal abscess in children is a ruptured appendix. A periappendiceal abscess is more commonly found in the pouch of Douglas or in the perihepatic space than in its expected location in the right iliac fossa because of the typical spread of infection in the peritoneal cavity.

Figure 58-20. Peritoneal abscess in the pouch of Douglas. CT scan through the pelvis of a patient with a ruptured appendix shows a peritoneal abscess in the pouch of Douglas.

Figure 58-19. Hypoperfusion complex. CT scans through the upper abdomen (*A*) and the midabdomen (*B*) in a patient following blunt trauma demonstrate diffuse intestinal dilatation with fluid; intense contrast enhancement of bowel wall, kidneys, and great vessels; and diminished caliber of great vessels, consistent with the hypoperfusion complex.

The CT appearance of a peritoneal abscess varies. It is typically well circumscribed and has a mass effect, displacing adjacent bowel loops (see Fig. 58-4).^{20, 21} The walls of the lesion are usually thick and may enhance. Variable attenuation is noted within the lesion, ranging from that of water to that of a solid or complex mass (see Fig. 58-20). Air may occasionally be noted within the abscess.

Peritonitis

Peritonitis may be primary (when the origin is outside the peritoneal cavity) or secondary (when it extends from a peritoneal source). Primary peritonitis usually spreads by blood or lymph. Secondary peritonitis can develop after extension from an intraperitoneal abscess or rupture of a hollow viscus. On a CT scan, the principal finding is peritoneal fluid of high attenuation (Fig. 58-21). Septations may be noted within the fluid. Nodularity and irregularity of the peritoneum may also be noted.

Neoplasms

Intraperitoneal neoplasms are usually secondary to metastatic disease. Primary neoplasms of the peritoneal cavity, which are rare in childhood, include cystic mesothelioma, yolk sac tumor, immature teratoma, and papillary cystadenoma.^{9, 30, 40, 53}

Peritoneal Metastases

Neoplasms involving the peritoneal cavity are usually metastases from the GI or genitourinary tract. The more common extraperitoneal neoplasms reported to metastasize to the peritoneal cavity include ovarian germ cell tumors, neuroblastoma, Wilms' tumor, and lymphoma.^{9, 50} Peritoneal invasion usually occurs after the neoplasm breaks through the organ capsule or spills at the time of surgery and spreads along the visceral peritoneum. Intraperitoneal metastases of intracranial tumors in children with ventriculoperitoneal shunts have also been described.⁹ The spread

Figure 58-21. Peritonitis. CT scan through the midabdomen of a patient with peritonitis shows a large amount of peritoneal fluid. The fluid demonstrates a mass effect on the bowel and mesentery.

Figure 58-22. Peritoneal implant. CT scan through the upper abdomen demonstrates a peritoneal implant in Morison's pouch.

of a neoplasm along the peritoneal cavity follows a pattern similar to that described for infection.

CT findings of peritoneal metastases include nodularity and irregularity of the peritoneum secondary to implants (Fig. 58-22), drop metastases into the pouch of Douglas (Fig. 58-23), and high-attenuation peritoneal fluid.^{9, 50, 58} Associated mesenteric and omental masses are also typically seen.

Cystic Mesothelioma

Cystic mesothelioma is a rare primary neoplasm of the peritoneal cavity in children. It is not related to asbestos exposure. It originates in the serous lining of the peritoneal space and shows predilection for the surfaces of the pelvic viscera.^{9, 30, 40} The CT scan appearance is that of a large, multiseptated cystic mass (Fig. 58-24). The neoplasm does not metastasize, but if it is not completely removed, it often recurs locally.

Figure 58-23. Drop metastasis into the pouch of Douglas. CT scan through the pelvis shows a large drop metastasis in the pouch of Douglas.

Figure 58-24. Peritoneal cystic mesothelioma. CT scan through the pelvis shows a large, multiseptated, cystic mass. At surgery, a cystic peritoneal mesothelioma was noted.

Trauma

Hemoperitoneum

Post-traumatic peritoneal fluid may represent blood, urine, third-space fluid losses, or bowel contents.^{11, 48} Peritoneal blood, or hemoperitoneum, is seen in association with approximately two thirds of all intraperitoneal solid-organ injuries.⁴⁸ Hemoperitoneum may not be present if the injury does not extend to the organ surface or if there is no capsular disruption.

The attenuation values of blood in the peritoneal cavity vary widely, depending on whether it is unclotted blood, clotted blood, or active hemorrhage. Unclotted hemoperitoneum has attenuation values of less than 60 Hounsfield units (HU) (Fig. 58-25). Clotted blood has higher attenuation values than unclotted hemoperitoneum because of its greater density and hemoglobin content (Fig. 58-26). Be-

Figure 58-25. Unclotted hemoperitoneum. CT scan through the midabdomen of a patient with hepatic injury following blunt abdominal trauma demonstrates low-attenuation, free hemoperitoneum in the right paracolic recess.

Figure 58-26. Clotted blood (sentinel clot). CT scan through the midabdomen in a patient following blunt abdominal trauma shows a well-circumscribed mesenteric hematoma. The hematoma has higher attenuation than free hemoperitoneum.

cause clotted blood is typically seen adjacent to the site of injury, the presence of focal higher-attenuation clotted blood (the sentinel clot sign) is a marker for the principal site of hemorrhage.³¹ Active hemorrhage is characterized by focal or diffuse, high-attenuation areas (>90 HU) following vascular enhancement (Fig. 58-27). It depends on the presence of brisk extravasation of contrast-enhanced blood.^{46, 56}

The amount of hemoperitoneum noted at CT is not a measure of ongoing hemorrhage but, instead, reflects the amount of blood that accumulated between the time of injury and the time the CT was obtained.⁴⁸ The peritoneal blood seen at CT may have accumulated in the first few minutes after the injury, or it may be continuing to accumulate. The only sign of active hemorrhage at CT is focal or diffuse, high-attenuation areas measuring over 90 HU and

Figure 58-27. Active hemorrhage. CT scan through the midabdomen demonstrates a focal area of high-attenuation fluid representing active hemorrhage from a torn mesenteric vessel. The surrounding intermediate-attenuation clotted blood can be seen.

representing extravasated intravascular contrast media mixed with blood (see Fig. 58–27).^{46, 56}

Mesentery and Omentum

Developmental Abnormalities

Midgut Malrotation

Malrotation of the small-bowel mesentery around the superior mesenteric artery occurs when the normal process of gut development is arrested during fetal development. In the first trimester, the duodenum fuses to the posterior body wall and becomes retroperitoneal, whereas the remainder of the small bowel and its mesentery herniates into the umbilical cord and undergoes a counterclockwise rotation about the superior mesenteric artery. The result is that the normal jejunoileal mesentery extends obliquely from the duodenal-jejunal junction in the left upper quadrant to the ileocecal valve in the right lower quadrant.

Arrest of this process leads to malrotation, which may result in intestinal obstruction secondary to remnant peritoneal folds (Ladd's bands) that cross the duodenum, or in twisting of the shortened mesentery with subsequent midgut volvulus. The most direct imaging technique for identifying midgut malrotation is a barium upper GI tract examination; however, the diagnosis can be strongly suggested at cross-sectional imaging. CT scan findings in midgut volvulus include reversal of the normal relationship between the superior mesenteric artery and vein (Fig. 58–28), and twisting of the mesentery around the artery, which creates a whirlpool appearance (Fig. 58–29).⁶⁰

Mesenteric Lymphangioma

A mesenteric lymphangioma, or mesenteric cyst, is a contiguous mass of dilated lymphatics. It occurs secondary to failure of lymphatic tissue within the mesentery and omentum to establish normal communication with the remainder of the lymphatic system during fetal develop-

Figure 58–28. Midgut malrotation. CT scan through the midabdomen in a patient with midgut malrotation demonstrates inversion of the superior mesenteric vessels, with the superior mesenteric vein positioned to the left of the superior mesenteric artery.

Figure 58–29. Midgut malrotation. CT scan through the midabdomen of a patient with midgut malrotation and volvulus demonstrates twisting of the small-bowel mesentery around the superior mesenteric artery.

ment.³⁷ Lymphangiomas arise within the small bowel mesentery, the mesocolon, or peritoneal reflections. The mass can become large, but because it is soft, it rarely results in bowel obstruction. Most patients present with a palpable mass.

The typical CT appearance of lymphangioma is that of a large, thin-walled, multiseptate cystic mass (Fig. 58–30).³⁷ The walls are occasionally thick and irregular, and calcifications may be noted in them. The internal fluid contents are usually homogeneous, and the attenuation varies from that of water to that of fat. Mesenteric lymphangiomas occasionally rupture, resulting in the presence of associated free peritoneal fluid.

Infection and Inflammation

Mesenteric Lymphadenopathy

Mesenteric lymph nodes are located adjacent to bowel wall along the ileal and jejunal arteries and superior mesen-

Figure 58–30. Mesenteric lymphangioma. CT scan through the pelvis shows a thin-walled, septate cystic mass.

Figure 58-31. Mesenteric lymphadenopathy. CT scan through the lower abdomen shows enlarged mesenteric lymph nodes in the right lower quadrant.

teric vein. Mesenteric lymphadenopathy is a nonspecific finding associated with a variety of abdominal or pelvic infectious, inflammatory, and neoplastic conditions.^{34, 45} The clinical syndrome of mesenteric lymphadenitis, which includes acute right lower quadrant pain and tenderness, fever, and leukocytosis, may mimic an acute abdomen. In several series, mesenteric lymphadenitis was the most frequent alternative diagnosis in children who underwent surgery because of suspected acute appendicitis.

Enlarged mesenteric lymph nodes measure greater than 5 mm in maximal diameter on the CT scan.^{34, 39} The lymph nodes are oval, homogeneous in attenuation, and generally seen in clusters (Fig. 58-31). The most common location is the right iliac fossa. Enlarged mesenteric lymph nodes may be noted as an isolated finding at CT or in conjunction with other pathology. The most frequent associated finding is small-bowel thickening related to an enteritis. Although enlarged mesenteric lymph nodes are generally considered to be simply a secondary finding and themselves insignificant, associated complications may be noted occasionally. These include abscess formation (suppurative mesenteric lymphadenitis) (Fig. 58-32), peritonitis, and mesenteric venous thrombosis.²

Segmental Omental Infarction

Segmental omental infarction is an uncommon condition that may present with the clinical signs and symptoms of an acute abdomen. The condition is generally managed nonoperatively. Proposed underlying causes of segmental omental infarction include omental torsion, trauma, thromboembolism, and prior surgery. It may also be idiopathic. The condition is more frequently right-sided.³³ The CT appearance of segmental omental infarction includes a focal area of well-circumscribed infiltration of omental fat with heterogeneous areas of increased attenuation (Fig. 58-33).³³ The range of the abnormality extends from anterior to the liver, inferiorly to the lower abdomen. Associated mass effect is often present on adjacent structures, including liver and bowel loops.

Figure 58-32. Suppurative mesenteric lymphadenopathy. CT scan through the lower abdomen shows a rounded, low-attenuation lesion with a thick, enhancing wall. At surgery, suppurative mesenteric lymphadenopathy was noted.

Neoplasms

The most common neoplasms that involve the mesentery and omentum in children are lymphoma, usually in the disseminated form, and metastases.

Lymphoma

Mesenteric involvement is more common in non-Hodgkin's lymphoma than in Hodgkin's disease. When mesen-

Figure 58-33. Segmental omental infarction. CT scan through the upper abdomen demonstrates well-circumscribed, focal infiltration of right-sided omental fat.

Figure 58-34. Rounded omental metastasis. CT scan through the upper abdomen demonstrates a rounded, heterogeneous mass in the lesser omentum, representing metastatic disease.

teric lymphadenopathy is observed in children with lymphoma, retroperitoneal lymph nodes are usually enlarged. The CT scan of metastatic disease in the mesentery and omentum varies from discrete masses that may be cakelike or rounded (Fig. 58-34), to ill-defined masses.^{9, 59} Infiltration of surrounding mesenteric fat may also be seen.

Primary Neoplasms

Primary mesenteric and omental neoplasms are rare. Those reported include fibroma, lipoma, lipoblastoma, desmoid tumor, Castleman's tumor, and yolk sac tumor.^{5, 9, 17, 25, 42} Fibroma, the most common primary mesenteric neoplasm, is typically well circumscribed, with homogeneous soft tissue attenuation at CT scan. The mesenteric lipoma is well circumscribed and homogeneous, with fat attenuation. Lipoblastoma has a heterogeneous appearance, with areas of soft tissue attenuation seen within a focal fatty mass. Desmoid tumors, which typically occur in postcolectomy patients with Gardner's syndrome,⁵ are large and highly infiltrative.

Castleman's disease, also known as giant lymph node hyperplasia or angiofollicular lymph node hyperplasia, is a rare benign condition (Fig. 58-35).¹⁷ It is most commonly noted in the mediastinum but in rare instances arises in extrathoracic sites containing lymphoid tissue, including the mesentery. The yolk sac tumor is a highly malignant entity that occasionally arises in the mesentery.²⁵

Trauma

Mesenteric Injury

Mesenteric injury may occur following blunt or penetrating trauma. It is often associated with bowel injury. Associated CT findings include mesenteric hematoma, infiltration of mesenteric fat, bowel wall enhancement, and unexplained peritoneal fluid (see Fig. 58-26).^{54, 57} It may be difficult to differentiate isolated mesenteric injury from bowel rupture with CT because similar findings may be

Figure 58-35. Castleman's disease of the mesentery. CT scan through the lower abdomen demonstrates a large, solid mass in the mesentery. At surgery, this was noted to be Castleman's disease.

noted in both entities. A late complication of mesenteric injury is intestinal stricture, probably resulting from associated bowel ischemia following the injury that heals by means of fibrosis, thus narrowing the intestinal lumen.⁴¹

Pediatric and Adolescent Pelvis

Marilyn J. Siegel

Computed tomography (CT) and magnetic resonance imaging (MRI) provide a useful adjunct to sonography in the evaluation of the pediatric and adolescent pelvis. Sonography remains the imaging study of choice for the initial assessment of suspected pelvic lesions, whereas CT and MRI are helpful in establishing the origin of a mass when the results of sonography are equivocal, to delineate the full extent of neoplastic or inflammatory lesions, and to characterize further müllerian malformations.^{4, 6, 16, 57-63, 65, 67} This chapter reviews the CT and MRI findings of the most common pelvic abnormalities in children. In particular, lesions of the genital tract, bladder, and pelvic soft tissues are addressed.

Patient Preparation: Technical Considerations

Computed Tomography

Oral Contrast Material

Oral contrast medium is routinely administered for pelvic CT examinations in order to opacify loops of small bowel lest they be mistaken for a mass lesion or abnormal fluid collection.⁶⁰ This is usually achieved by giving the patient a dilute contrast agent by mouth or through a nasogastric tube at least 1 hour before the start of the study. To increase patient compliance, the contrast agent can be mixed with fruit juice. The volume of contrast medium varies with the age of the patient (Table 59-1).

Despite the administration of a relatively large amount of contrast medium, the descending and rectosigmoid colon often remain unopacified. Although these segments can be recognized by their relatively fixed location and fecal contents, their opacification is sometimes desirable. Opacification of the distal colon can be achieved by administering additional oral contrast medium and then rescanning the patient after a suitable delay to allow the contrast agent to pass distally. Alternatively, a contrast enema can be administered to expedite opacification of these segments.

Table 59-1. Oral Contrast Doses Versus Patient Age

Age	Minimum Amount Given at Least 1 Hour Before Scanning
<1 mo	2-3 oz (60-90 mL)
1 mo to 1 yr	4-8 oz (120-240 mL)
1-5 yr	8-16 oz (240-480 mL)
6-12 yr	16-24 oz (480-720 mL)
≥13 yr	24-36 oz (720-1000 mL)

Intravenous Contrast Material

Differentiation of the pelvic vessels from enlarged lymph nodes is facilitated by the use of intravenous (IV) contrast medium.⁶⁰ The recommended dose of contrast is 2 mL/kg, not to exceed a total of 4 mL/kg or 100 mL (whichever is the lesser amount). Contrast medium may be administered by hand injection or via a mechanical injector. The latter type of administration is preferred if a 22-gauge or larger angiocatheter can be placed in an antecubital vein. A flow rate of 1.2 to 1.5 mL/sec is acceptable for a 22-gauge angiocatheter, whereas a rate of 2.0 mL/sec is recommended for 20-gauge catheters. Hand injection is preferred for smaller-caliber needles in the antecubital region and for needles positioned in the hand.

The initiation of scanning should be delayed until 60 to 75 seconds after the start of the contrast medium bolus to ensure opacification of pelvic vessels. Because the initial scans are obtained before significant contrast medium excretion has occurred, the ureters and bladder are not usually opacified. Delayed scanning at 3 to 5 minutes allows contrast medium to accumulate in the bladder, facilitating the recognition of pelvic fluid collections and bladder pathology.

Imaging Technique

For routine pelvic studies, contiguous 5- to 8-mm scans usually suffice. Decreased collimation (2 to 4 mm) is reserved for infants and very small children, for areas of maximum interest, and for detailed examinations of smaller structures. If the patient is cooperative, CT sections are obtained with breath-holding at suspended inspiration. If the patient is sedated or unable to suspend respiration, CT sections are obtained at resting lung volume.

Magnetic Resonance Imaging

The pelvis also can be successfully evaluated with MRI. Unlike the procedure in CT, oral contrast medium is not routinely administered for MRI examinations.

Coil Selection

For optimal signal-to-noise ratio and spatial resolution, MRI examinations of the pelvis should be performed with the smallest receiver coil that fits tightly around the body part being studied. A head coil or phased-array coil is used in most infants and small children, whereas a phased-array or whole-body coil is the receiver coil of choice for imaging larger children and adolescents. Phased-array coils

are preferred over body coils for imaging of the pelvis because they provide better anatomic resolution.

Slice Thickness and Matrix

Slice thickness varies with patient size and the area of interest. A slice thickness of 4 to 8 mm obtained at 5- to 10-mm intervals is usually adequate for a general survey of the pelvis and larger lesions. Thinner slices obtained at 4 mm are particularly useful for evaluating small lesions and through areas of maximum interest. A 128 or 192 matrix and one or two signal acquisitions generally are used in pediatric MRI examinations to shorten imaging time, although a 286×286 matrix may be needed in areas where more anatomic detail is desired.

Pulse Sequences

Both T1-weighted and T2-weighted sequences are required to image the pelvis. *T1-weighted sequences* (short repetition time [TR], short echo time [TE]) exploit the contrast differences between soft tissue structures and fat and are used to increase lesion detection and to characterize hemorrhagic and fatty components of pelvic masses.

T2-weighted sequences (long TR, long TE) provide excellent contrast between tumor and adjacent soft tissues and are useful for tissue characterization. Fast spin-echo techniques have virtually replaced conventional T2-weighted sequences. The fast spin-echo techniques substantially reduce imaging time, although they may result in slight loss of contrast between fat and other similarly intense fluid and tissues. To increase the contrast range of nonfatty tissue and to reduce or minimize ghost and chemical shift artifacts, the T2-weighted fast spin-echo sequences should be performed with fat-suppression techniques.

Fat-suppressed sequences are useful to increase contrast between normal and pathologic tissue on T2-weighted images and to improve lesion conspicuity. Fat suppression can be accomplished with either short tau inversion recovery (STIR) or radiofrequency presaturation of the lipid peak (fat saturation). Signal from fat is made null on STIR and fat-saturated images, whereas pathologic lesions have prolonged T1 and T2 values secondary to increased free water and are bright on the fat-suppressed sequences.

Optional imaging sequences include the *gradient-echo* technique and *contrast-enhanced imaging*. The gradient-echo sequence results in high signal in flowing blood and is useful in evaluating the patency of blood vessels and in differentiating vessels and lymph nodes.⁵⁵ The relatively short acquisition time required for gradient-echo images also allows serial dynamic imaging immediately after IV administration of a gadolinium (Gd) chelate agent. The Gd-enhanced images can provide additional information about the character of neoplasms and the relationship of neoplasms to adjacent pelvic structures.

Imaging Planes

Transaxial images are routinely obtained in pelvic MRI examinations. These images are useful for displaying the contour and anatomy of the bladder, uterus, and prostate and for assessing tumor extension to the pelvic side walls. In most instances, additional images are obtained in either the coronal or sagittal planes. Coronal images are useful for defining the relationship of the uterus and prostate to

adjacent vessels, viscera, and pelvic floor and for demonstrating pelvic side wall invasion and lymphadenopathy. Sagittal images are best for evaluating the uterine fundus, vagina, rectum, spine, and presacral soft tissues.

Normal Anatomy

Female Pelvis

Ovaries

The ovaries descend from the upper abdomen into the pelvis during fetal life. With activation of the hypothalamic-pituitary-ovarian axis at the time of puberty, the ovaries move deeper into the pelvis, reaching their adult position posterolateral to the body of the uterus, although not necessarily at the same horizontal level. In some individuals, descent is incomplete, and the ovaries remain high in the pelvis, lying dorsal or cephalad to the uterus. They may be seen posterior to the uterus if ligamentous attachments are lax.

On both CT and MRI, the ovaries and uterus are identified more often in menarchal girls than in prepubertal girls. Cystic structures, representing follicles, can be seen in more than 70% of girls, regardless of age⁵³ (Fig. 59-1). In premenarchal girls, these cysts represent unstimulated (primordial) follicles; in menarchal girls, they may represent either unstimulated or stimulated (graafian or corpus luteum) follicles.⁵³ Unstimulated follicles usually have a diameter of less than 9 mm (Fig. 59-1A and B). Developing graafian or corpus luteum follicles range between 9 mm and 3 cm in diameter (Fig. 59-1C). A cystic mass larger than 3 cm in diameter is considered pathologic and usually represents a stimulated follicle that failed to involute.

Mean ovarian volumes on CT range between 0.4 and 0.8 cm³ in girls younger than 8 years and between 2.1 and 6.9 cm³ in girls 9 years of age or older.⁵³

On T1-weighted MR images, the normal ovaries have a low to medium signal intensity and are isointense relative to uterine myometrium and to skeletal muscle. On T2-weighted images, the follicles increase in signal intensity and are hyperintense to fat, whereas the ovarian stroma becomes isointense or hyperintense to myometrium (Fig. 59-2).

Uterus and Vagina

Computed Tomography

The neonatal uterus is relatively large because of in utero stimulation by maternal hormones. During the first month of life, the uterus decreases in size as the level of exogenous hormones declines. In prepubertal girls, the uterus appears as a homogeneous, oval soft tissue structure posterior to the bladder; zonal anatomy is not evident (Fig. 59-3). As puberty approaches, the uterus begins to increase in size, with the corpus becoming thicker and larger than the cervix, producing the adult pear-shaped uterus. In the postmenarchal girl, the uterus is seen as an oval or a triangular soft tissue structure. Zonal anatomy may be recognized after the IV administration of contrast medium. On contrast-enhanced scans, the myometrium and endometrium show intense enhancement, and although they cannot be differentiated from each other, they can be differentiated

Figure 59-1. Normal postmenarchal female pelvis. A and B, Contrast-enhanced CT scans of a 15-year-old girl show low-attenuation ovaries (arrowheads) and an oval uterine fundus that demonstrates zonal differentiation. The higher-attenuation myometrium and endometrium can be differentiated from the lower-attenuation endometrial canal (e), but they cannot be differentiated from each other. C, CT scan of a different 15-year-old girl on day 12 of the menstrual cycle demonstrates a cystic structure (arrow) in the right ovary, representing a developing follicle. The diameter of the cyst is 2.0 cm. U, uterus.

from the lower-attenuation endometrial cavity (see Fig. 59-1A and B). The hypodensity centrally reflects the presence of secretions or blood.

The mean uterine volumes reported on CT examinations of pediatric patients range between 0.5 and 1.3 cm³ in girls younger than 8 years of age and between 4.1 and 37.3 cm³ in older girls.⁵³

Although there are no clear-cut planes between the cervix and vagina, they usually can be distinguished by their shape. The cervix has a rounded appearance, whereas the vagina usually appears as a flat rectangular structure. On contrast-enhanced CT scans, the central portions of the cervix and vagina enhance, reflecting their mucosal lining.

Magnetic Resonance Imaging

On MRI scans, the uterus, cervix, and vagina of the premenarchal girl have a relatively low to medium signal intensity and indistinct zonal anatomy. In pubertal girls,

the uterus has a homogeneous medium signal intensity on T1-weighted images. The characteristic zonal anatomy usually can be seen on T2-weighted images.^{40, 41} The central high-signal-intensity zone represents the endometrium, the adjacent low-signal-intensity layer corresponds to the inner myometrium, and the peripheral intermediate-signal-intensity layer corresponds to the outer myometrium (see Fig. 59-2). Endometrial width normally varies during the menstrual cycle; it is thinnest immediately after menses and is thickest at midcycle.

The cervix has a homogeneous low to intermediate signal intensity on T1-weighted images. Three zones are seen on T2-weighted images: the high signal intensity central canal, an adjacent low signal intensity layer, and an outermost medium signal intensity layer. Like the uterus and cervix, the vagina also has an intermediate signal intensity on T1-weighted images. Two zones are seen on T2-weighted images: the central high-signal-intensity canal and the intermediate-signal-intensity wall.⁴⁰

Figure 59-2. Normal postmenarchal female pelvis. T2-weighted fat-saturated (3500/98/180 degrees) MR image of a 14-year-old girl demonstrates that both ovaries have relatively high signal intensity (arrowheads), reflecting the presence of multiple follicles. Some intermediate-signal-intensity stromal tissue can be noted in the left ovary posteriorly. Note the zonal anatomy of the uterus. e, endometrial canal; m, myometrium. Arrow indicates junctional zone.

Figure 59-3. Normal prepubertal female pelvis. CT scan of a 7-year-old girl. The uterus (U) appears as a homogeneous, oval soft tissue structure posterior to the bladder. The endometrial cavity is indistinguishable from the myometrium. Neither ovary is visualized. The normal bladder wall is thin. On this contrast-enhanced scan, the opacified urine occupies the dependent portion of the bladder and unopacified urine layers are above it. A Foley catheter (F) is present, accounting for the air-fluid level (open arrows).

Male Pelvis

The prostate gland and seminal vesicles are usually too small to be appreciated on routine pelvic CT or MRI studies in infants and young boys. Because these structures increase in size at the time of puberty, they are easier to recognize on routine examinations.

The prostate gland lies posterior to the symphysis pubis and anterior to the rectum. In prepubertal boys, it usually appears as a homogeneous soft tissue attenuation structure on both noncontrast and contrast-enhanced CT scans and MRI. In pubertal boys, zonal anatomy may be seen on some contrast-enhanced CT and MRI examinations (Fig. 59-4).

The seminal vesicles are located posterior to the urinary bladder, cephalic to the prostate gland, and anterior to the rectum. They are seen on CT as soft tissue structures with oval or bow-tie configurations. They have a low to medium signal intensity on T1-weighted images and a high signal intensity on T2-weighted images. The spermatic cords are found anterolateral to the symphysis pubis and medial to the femoral veins. They appear either as oval or round homogeneous soft tissue structures or as thin-walled, ring-like structures containing fat, vessels, and the vas deferens.

Urinary Bladder

The urinary bladder is a midline structure with varying size and configuration depending on the degree of distention. The bladder wall has an attenuation value or signal intensity equal to that of soft tissue, whereas the urine has an attenuation value or signal intensity near that of water.

Other Structures

The pelvic muscles (psoas, iliacus, obturator internus, pyriformis, and levator ani) are symmetrical in size and

Figure 59-4. Normal male pelvis. Transaxial T2-weighted fast spin-echo MR image (2500/90) through the pubic symphysis in a 14-year-old boy shows the high-signal-intensity peripheral zone (curved arrows) of the prostate and the lower-signal-intensity central gland. BL, bladder.

shape in normal individuals. Small-bowel loops and the rectum, ascending, descending, and sigmoid colon are easily seen, especially on CT when the bowel lumen is distended with contrast medium. Normal pelvic lymph nodes are not routinely recognized on CT or MRI examinations in children.

Congenital Anomalies

Imaging Approach

Ultrasonography and MRI have both been shown to be useful methods of evaluating patients with suspected uterine or vaginal anomalies.^{11, 20, 30, 31, 40, 42, 43, 52, 59} Hysterosalpingography also is a well-established technique for evaluating uterine anomalies, but since the advent of MRI, it is not usually needed for diagnosis. CT can be used to detect and differentiate congenital anomalies, although it is not performed as routinely as MRI because it uses ionizing radiation and has suboptimal soft tissue contrast compared with MRI.

Ultrasonography, especially transvaginal sonography, probably is the best initial examination in the evaluation of patients with suspected uterine anomalies because it is widely available and relatively lower in cost than MRI.³¹ If the results of sonography are indeterminate or if additional information is needed to characterize an anomaly seen on sonography, MRI is indicated. In one series that compared transvaginal sonography, MRI, and hysterosalpingography, the accuracy of MRI for diagnosis of uterine anomalies was 100%, 90% for sonography, and 30% for hysterosalpingography.⁴⁸

MRI Techniques

The MRI examination of suspected müllerian anomalies should include the following³¹:

1. A T1-weighted coronal image of the abdomen to show the size, shape, and position of the kidneys.
2. T1-weighted axial and sagittal images of the pelvis to show the relationship of the obstructed uterus to the vagina and the presence of subacute blood products.
3. A T2-weighted fast spin-echo sagittal scan to show the length and contour of the vaginal canal and uterine zonal anatomy.
4. A T2-weighted fast spin-echo axial image to show communication between the two parts of a unicornuate, bicornuate, or didelphys uterus and the location of the ovaries.
5. An off-axis coronal scan to show the contour of the fundus.

Imaging of the upper urinary tract is important because 20% to 25% of all patients with uterine anomalies have concomitant urinary tract anomalies.^{28, 42}

Uterine Anomalies

Classification

The prevalence of uterine malformations is 0.1% to 0.5%.^{11, 40, 42, 43} The spectrum of anomalies includes agene-

sis, hypoplasia, and duplication. Although a number of systems have been proposed for classifying müllerian anomalies, the system most widely in use today is the one presented by the American Fertility Society.¹ This classification, based on the degree of failure of normal development, has seven major subgroups:

- I, segmental agenesis or hypoplasia (cervical, fundal, tubal, or combined anomalies)
- II, unicornuate uterus
- III, didelphys uterus
- IV, bicornuate uterus
- V, septate uterus
- VI, arcuate uterus
- VII, diethylstilbestrol (DES)-related uterine hypoplasia with luminal changes

The most common abnormalities, which include agenesis/hypoplasia, unicornuate uterus, and the duplication anomalies (didelphys, bicornuate, and septate), are discussed later.

Embryology

The uterus, fallopian tubes, cervix, and upper part of the vagina develop from the paired müllerian ducts. The ducts descend into the pelvis from the upper abdomen, migrate into the midline, and fuse medially at about the 10th week of fetal life.^{25, 31} The union of the two müllerian ducts begins in the lower half of the uterus and extends cephalocaudally. The septum between the two uterine bodies involutes and usually disappears by the 20th week of fetal life, leaving behind the fully developed fallopian tubes, uterus, and proximal vagina. Developmental anomalies result when there is failure of ductal fusion or incomplete septal regression.

The lower two thirds of the vaginal canal forms from the sinovaginal bulb. The distal and proximal parts of the vagina ultimately communicate when a cell cord between the two dissolves. Failure of normal development can result in vaginal hypoplasia or agenesis or a septum within the vaginal canal.

Specific Anomalies

Uterine Agenesis and Hypoplasia

Uterine agenesis and hypoplasia are the result of arrested development of the müllerian ducts bilaterally. This can be an isolated finding, or it may occur in association with the *Mayer-Rokitansky-Küster-Hauser syndrome*. Patients with arrested development of the müllerian ducts most commonly present with primary amenorrhea.⁵²

The Mayer-Rokitansky-Küster-Hauser syndrome is characterized by vaginal atresia and a spectrum of uterine anomalies, including absence, hypoplasia, and duplication.^{19, 52} Patients have a normal female karyotype, external genitalia, and secondary sexual development and normal ovaries and fallopian tubes. Renal anomalies, usually agenesis and rarely ectopia or hydronephrosis, occur in about 50% of patients, and skeletal anomalies occur in about 15% of patients.

MRI is particularly well suited to show uterine size, the degree of zonal differentiation, and the absence of the vaginal stripe. In addition to its small size, the hypoplastic

Figure 59-5. Mayer-Rokitansky-Küster-Hauser syndrome in a 16-year-old girl with amenorrhea. A, Coronal T1-weighted image (600/30) shows a low-signal-intensity uterus (U). B, Sagittal T2-weighted image (2500/90) shows absence of the vaginal canal and a hypoplastic uterus (U) with absent zonal differentiation. This patient has normal ovaries and no associated renal anomalies. Arrows indicate the urethra.

uterus exhibits poorly differentiated zonal anatomy, abnormally low signal intensity of the myometrium on T2-weighted sequence, and reduced endometrial and myometrial width¹¹ (Fig. 59-5).

Possible diagnoses to be considered in patients with this syndrome include primary vaginal atresia with a patent endometrial canal and cervix (see later) and congenital disorders of sexual differentiation, such as Turner's syndrome (45 XO karyotype, streak ovaries), true hermaphroditism, and the testicular feminization syndrome.⁵² The latter syndrome results from the absence of testosterone receptors and is characterized by a male karyotype, testes that may be maldescended, female external genitalia, a blind-ending vagina that may be shortened, and an absent uterus. The role of MRI in these patients is to depict the pelvic anatomy and to identify abnormally developed or positioned gonads.

Unicornuate Uterus

The unicornuate uterus results from failure of development of one of the two müllerian ducts. The affected hemiuterus may have a communicating rudimentary horn or a noncommunicating rudimentary horn (Fig. 59-6), or it may be absent.¹¹ The rudimentary horn, communication between the two horns, and size of the endometrial cavity are best appreciated on T2-weighted images. Renal anomalies occur in about 25% of cases. Unicornuate uterus is not usually treated surgically.³¹

Uterus Didelphys

The anomaly known as uterus didelphys is characterized by complete duplication of the uterine body and cervix

resulting from nonfusion of the müllerian ducts. Patients are usually asymptomatic unless an associated vaginal septum is causing hematocolpos. MRI shows two separate normal-sized uterine bodies, two cervices, and in many cases an upper longitudinal vaginal septum.¹¹ The uterine

Figure 59-6. Unicornuate uterus with a noncommunicating rudimentary horn. An off-axis (oblique) T2-weighted fat-saturated image (TR 3500/TE 90/180 degrees) shows a hypoplastic left uterine horn (curved arrow) that does not communicate with the normal right uterine horn (arrowheads). Both uterine horns are deviated laterally.

Figure 59-7. Uterus didelphys. Axial T1-weighted (600/15) MR image demonstrates duplicated uterine horns (H) with a widened intercornual distance. Fatty tissue is noted between the two horns. The high-signal-intensity focus within the right endometrial cavity represents blood. (From Siegel MJ: Pediatric applications. In Lee KRL, Sagel SS, Stanley RJ, Heiken JP [eds]: *Computed Body Tomography with MRI Correlation*. Philadelphia, Lippincott-Raven, 1998, p 1549.)

horns are widely divergent with an intercornual angle of more than 75 degrees (Fig. 59-7). Each horn has a fusiform shape, convex lateral margins, and a central endometrial cavity surrounded by a junctional zone. In each uterus, the endometrial-myometrial width and ratio are preserved.¹¹ There is no effective surgical repair for uterus didelphys.

Bicornuate Uterus

The anomaly known as bicornuate uterus is due to a lack of fusion of the uterine corpus; there is a single cervix (Fig. 59-8). MRI features of a bicornuate uterus are a concave fundal contour (instead of the normal outward fundal convexity) and a deep cleft (>1 cm) between the two uterine bodies.^{11, 28, 43} The tissue between the two horns is composed of myometrium and thus typically enhances on CT (see Fig. 59-8); it has an intermediate signal intensity on T1-weighted images and a higher signal intensity on T2-weighted images. The endometrial-myometrial ratio and width are normal.¹¹ The bicornuate uterus is treated with transabdominal surgical resection of the muscular division between the two sides of the uterus to fuse the two horns (metroplasty).

Septate Uterus

The septate uterus is the most common müllerian anomaly. It is characterized by a single uterus, cervix, and vagina with a septum that divides the uterus into two compartments. The anomaly results from partial or complete failure of resorption of the midline septum. On MRI scans, there is a single uterine fundus with a normal convex fundal contour or minimal (>1 cm) concavity and a normal intercornual distance.¹¹ Signal intensity of the septum depends on the relative amounts of fibrous tissue or myometrium. A fibrous septum has a relatively low signal intensity

Figure 59-8. Bicornuate uterus. T2-weighted (2500/90) MR image shows two uterine bodies (arrows) separated by intermediate-signal-intensity myometrium. The fundal contour is concave, and there is a deep cleft between the two uterine horns. The uterine horns are of a similar size and have differentiated zonal anatomy. The high-signal-intensity fluid collection to the left of the duplicated uterus represents a lymphocele (L). BL, bladder.

on both T1-weighted and T2-weighted sequences, whereas myometrium has a bright signal on T2-weighted images (Fig. 59-9). The treatment of the septate uterus is hysteroscopic metroplasty.¹¹

Vaginal Anomalies

Congenital Vaginal Obstruction

Congenital anomalies of the vagina can be classified into two groups: those in which the vagina is absent and those in which the vagina is obstructed because of transverse membranes or septa. Vaginal atresia is the result of arrested development of the sinovaginal bulb or primitive vagina, whereas the development of transverse vaginal membranes or septa is secondary to errors in canalization.

Vaginal obstruction can be encountered in the neonatal period or at menarche. In the neonate, vaginal obstruction is caused by vaginal or cervical atresia, high-grade stenosis, a transverse septum, or an imperforate membrane. In adolescent girls, vaginal obstruction is most often the result of a simple imperforate membrane or septum. Affected neonates present with a palpable pelvic or abdominal mass resulting from the production and excessive accumulation of vaginal and/or uterine secretions in utero secondary to maternal hormone stimulation. Adolescent patients present with cyclic lower abdominal pain or a mass and a history of absent menses. There is an increased association of congenital anomalies (e.g., imperforate anus, esophageal or duodenal atresia, congenital heart disease, and renal abnormalities) in neonates with vaginal atresia but not in patients with imperforate hymen.

Figure 59-9. Septate uterus in a 15-year-old girl. T2-weighted (2500/90) MR image shows duplicated uterine cavities (c). The uterine contour (arrowheads) is normal. The septum has an intermediate signal intensity because it contains some myometrial tissue. The rectum (R) is dilated because of rectal stenosis related to repair of imperforate anus. The diagnosis of septate uterus is best made on the basis of demonstration of a normal or minimally concave fundus. BL, bladder. (From Siegel MJ: Pediatric applications. In Lee KRL, Sagel SS, Stanley RJ, Heiken JP [eds]: Computed Body Tomography with MRI Correlation. Philadelphia, Lippincott-Raven, 1998, p 1549.)

The CT findings of *hydrocolpos* (dilated vagina) or *hydrometrocolpos* (dilated vagina and uterus) are those of a tubular, fluid-filled, midline mass between the bladder and rectum. The distended vagina has a thin, barely perceptible wall, whereas the uterus has a thicker muscular wall that enhances after IV administration of contrast medium. The MRI appearance of hydrocolpos and hydrometrocolpos varies with the nature of the vaginal contents. Serous fluid has a low signal intensity on T1-weighted images and a high signal intensity on T2-weighted images (Fig. 59-10). The signal intensity increases on T1-weighted images if the contents are hemorrhagic.³⁰ Additional findings on CT and MRI include hydrosalpinx or hematosalpinx, ureterectasis, and hydronephrosis.

Pelvic Masses

Masses within the osseous pelvis may arise in the anterior pelvis and be of gynecologic, nodal, or lower urinary tract origin, or they may arise in the presacral space. The latter tumors are neurogenic or embryonic in origin. When a pelvic mass is detected on physical examination or another radiologic study, further characterization of the mass and delineation of its cause and extent are possible with ultrasonography, CT, and MRI.^{57-63, 65, 67}

Ultrasonography is used initially in the evaluation of most children with a suspected pelvic mass because it is easy to perform and ionizing radiation is not required. It is

Figure 59-10. Hydrocolpos in a young girl with a large pelvic mass after resection of a sacrococcygeal teratoma. Sagittal T2-weighted fat-saturated (5000/120/180 degrees) image shows high-signal-intensity fluid in the dilated vaginal canal (V) posterior to the bladder (B). The hypointense band overlying the distal vagina represents a susceptibility artifact from a metallic clip.

accurate in the diagnosis of gynecologic disease, but it is not as useful in determining the extent of gynecologic disease or in identifying presacral masses. Both CT and MRI can delineate the size and character of a mass and its relationship to adjacent pelvic viscera and soft tissue structures. In general, CT is more sensitive than MRI in demonstrating bone involvement, calcifications, and gas bubbles, whereas MRI is superior in detecting soft tissue invasion and bone marrow alterations and in displaying the extent of a presacral mass. CT is recommended for staging patients with gynecologic malignancies; MRI is preferred in patients with presacral mass lesions.

Ovarian Masses

Ovarian Cysts

Follicular and Corpus Luteum Cysts

Non-neoplastic cysts account for 25% to 35% of ovarian masses in children, of which half are follicular and half are luteal or paraovarian cysts.⁵⁰ Follicular and corpus luteum cysts result when a follicle continues to grow after failed ovulation or fails to collapse after ovulation occurs. The cysts can vary in size from 3 to 20 cm, but most are usually between 3 and 5 cm.⁵⁹ *Follicular cysts* contain clear serous fluid. *Corpus luteal cysts* can contain serous or hemorrhagic fluid. Both types of cysts may be discovered incidentally by pelvic ultrasonography, CT, or MRI, or they

may present as lower abdominal or pelvic pain secondary to mass effect, hemorrhage, or torsion.

CT is not usually needed for diagnosis, but recognition of the appearance of ovarian cysts is important because they are often unsuspected findings on CT studies obtained for other clinical indications. In patients with large ovarian cysts, CT may be requested as a primary study to document the exact location or extent of the cyst before aspiration or surgery.

Uncomplicated ovarian cysts appear as well-circumscribed, low-attenuation (<20 Hounsfield units) unilocular masses with thin walls that do not enhance after IV contrast administration (Fig. 59–11). A fluid-debris level, septa, or thick walls should raise the suspicion of a hemorrhagic cyst or adnexal torsion with the cyst acting as a fulcrum (Fig. 59–12). On MRI, the cysts demonstrate a low signal intensity on T1-weighted images and a high signal intensity on T2-weighted sequences.^{45, 78} Follicular and corpus luteal cysts cannot be differentiated on the basis of the CT findings alone. Both types of cysts usually involute spontaneously.

Multiple Ovarian Cysts

The differential diagnosis of the ovary with multiple follicles includes theca-lutein cysts and the spectrum of polycystic ovary disease.

Theca-lutein cysts are believed to represent hyperstimulated follicles and are most often seen in adolescent girls or women who have gestational trophoblastic disease or who are taking drugs to stimulate ovulation. In patients with theca-lutein cysts, both ovaries are enlarged and contain multiple cysts. Other ancillary findings are those re-

Figure 59–11. Benign ovarian cyst. Contrast-enhanced CT scan of a 14-year-old girl with pelvic pain and a mass shows a well-circumscribed, round, nonenhancing mass of near-water attenuation arising from the right ovary consistent with a cyst (C). The cyst measures 5 × 4 cm. Note the normal uterus and left ovary (arrow). BL, bladder.

Figure 59–12. Atypical ovarian cyst secondary to torsion. Contrast-enhanced CT scan in a 13-year-old girl shows a cystic mass (C) with thick enhancing walls posterior to the urinary bladder. A torsed right ovary containing a hemorrhagic corpus lutein cyst was found at surgery.

lated to the molar pregnancy, which include an enlarged, thick-walled uterus and dilated parametrial vessels.

Polycystic ovary disease, also known as the *Stein-Leventhal syndrome*, is characterized by amenorrhea, obesity, hirsutism, and chronic anovulation. Consistent pathologic features are hyperstimulated ovarian stroma and an increased number of immature and atretic follicles.

The characteristic CT findings of gestational trophoblastic disease and polycystic ovary disease are bilaterally enlarged ovaries that contain multiple small cysts.^{15, 44} In some patients with cystic ovary disease, the ovaries may be of normal size or the cysts may be too small to be recognized on CT or MRI, and the diagnosis can be made only with biopsy.

Hemorrhagic Cysts

Hemorrhagic cysts develop when blood vessels within a follicular or corpus luteal cyst rupture. Patients may present with the sudden onset of pelvic pain. The appearance of hemorrhagic cysts on CT and MRI depends on the age of the clot. On CT scan, acute hemorrhage has a high attenuation value; old blood has an attenuation value near that of water density. On MRI, subacute blood is typically bright on both T1-weighted and T2-weighted images, related to the formation of methemoglobin.^{45, 78} Acute blood that contains intact red blood cells can have a high signal on T1-weighted images but a low signal intensity on T2-weighted or gradient-echo images. The high signal intensity of subacute blood on T1-weighted images can mimic the appearance of fat.

Fat-suppressed and gradient-echo images can help to differentiate between hemorrhagic cysts and fat-containing tumors, such as teratomas. Serial imaging, usually with sonography, also can be useful to exclude neoplasm. Most

hemorrhagic ovarian cysts resolve in one or two menstrual cycles, whereas tumor remains unchanged or increases in size.

Ovarian Tumors

Approximately 65% to 80% of ovarian tumors are true neoplasms, of which approximately 65% are benign and the remainder are malignant.^{8, 17, 50} The most common benign ovarian tumor is a *cystic teratoma*. *Cystadenomas* occur less frequently.

Cystic Teratoma

Ovarian teratomas (cystic teratomas, dermoid cysts) are congenital lesions that contain tissue derivatives from all three germ cell layers (endoderm, ectoderm, and mesoderm). On pathologic examination, teratomas are subdivided into mature, immature (containing embryonic neural elements), and malignant types.^{8, 13} The first subtype accounts for more than 90% of ovarian germ cell tumors. Ovarian teratomas usually present as a pelvic or an abdominal mass, but they may produce pain if the tumor undergoes torsion, rupture, or hemorrhage. They usually range in diameter from 5 to 10 cm and are bilateral in 25% of cases.

On CT scans, the benign teratoma appears typically as a well-circumscribed, predominantly cystic mass (i.e., <50% soft tissue elements) that has smooth walls (2 to 5 mm thick). A specific diagnosis of a benign ovarian teratoma can be made on CT or MRI when fatty elements or a combination of fatty and calcific elements are identified within a predominantly cystic mass^{9, 51, 56} (Fig. 59–13). In one series of 43 cystic teratomas (41 benign and 2 malignant) imaged with CT, fat was seen in 93%, Rokitansky protuberances in 81%, teeth or calcific elements in 56%, and a fat-fluid level in 12% of lesions.⁹ Calcific elements and fat are usually located in the Rokitansky protuberance or dermoid plug arising from the cyst wall. Occasionally, the intracystic fat is mobile and shifts position.⁴⁶

Typically, benign teratomas are predominantly hypointense on T1-weighted images and markedly hyperintense on T2-weighted images, indicating that the cystic cavity contains aqueous fluid.^{45, 70, 77} Foci of fatty tissue have a high signal intensity on both T1-weighted and T2-weighted images, whereas calcifications, teeth, bone, hair, and fibrous tissue show low signal intensity on both pulse sequences. Gradient-echo and fat-suppression techniques are the best sequences to confirm the presence of lipid contents.⁶⁶ Other MRI findings of cystic teratomas include fat-fluid levels and gravity-dependent or floating debris.⁷⁰

Malignant Neoplasms

Ovarian tumors account for 1% to 2% of malignant neoplasms in girls younger than age 17 years.^{8, 12, 13, 50} Germ cell tumors (dysgerminoma, immature or malignant teratoma, endodermal sinus tumor, embryonal carcinoma, and choriocarcinoma) account for 60% to 90% of malignant neoplasms; stromal tumors (Sertoli-Leydig cell, granulosa-theca cell, and undifferentiated neoplasms) have a 10% to 13% incidence; and epithelial carcinomas account for 5% to 11% of malignant ovarian lesions.^{8, 13, 17, 50}

Most ovarian neoplasms present in adolescent girls as asymptomatic pelvic or abdominal masses. Isosexual precocity may be a presenting sign in patients with granulosa-theca cell tumors, whereas virilization may be observed in patients with Sertoli-Leydig cell tumors.^{12, 13} Levels of alpha-fetoprotein can be elevated in patients with endodermal sinus tumors, whereas levels of beta-human chorionic gonadotropin levels increase in patients with embryonal carcinoma and choriocarcinoma.⁵⁰ Treatment is by complete resection when possible. Otherwise, surgical debulking or biopsy is performed, followed by chemotherapy and definitive resection.

In general, malignant ovarian lesions appear as large, solid masses (>50% soft tissue elements) with thick, irregular walls.^{7, 10} Other common findings include focal low-

Figure 59–13. Benign ovarian teratoma in 15-year-old girl with pelvic pain. A, Contrast-enhanced CT shows a well-defined, low-attenuation mass anterior to the sigmoid (S) colon. Toothlike calcifications and fatty tissue are seen within the mass. On pathologic section, the teratoma contained predominantly sebaceous fluid and small amounts of hair, bone, and fat within several mural nodules. B, CT scan in another patient shows a low-attenuation mass with a septation and an intracystic fat ball.

Figure 59-14. Malignant ovarian germ cell tumors. *A*, Teratocarcinoma in a 11-year-old girl. CT scan shows a large solid mass with large amounts of calcification and scattered areas of fatty tissue (*arrowheads*). *B*, Dysgerminoma in a 13-year-old girl. Contrast-enhanced CT demonstrates a bulky, slightly heterogeneous mass (*M*) of soft tissue attenuation in the anterior pelvis.

attenuation areas due to necrosis or hemorrhage, calcifications, thick septa, and papillary projections^{7, 10, 51} (Fig. 59-14). On MRI, malignant ovarian neoplasms have a low to intermediate signal intensity on T1-weighted images and intermediate or high signal intensity on T2-weighted images.²⁴

The malignant germ cell and stromal neoplasms spread by contiguous extension, by lymphogenous spread to regional or distant lymph nodes, or by hematogenous dissemination to lungs or liver. Ovarian carcinomas tend to spread by seeding the peritoneal or omental surfaces. Peritoneal tumor implants are seen as soft tissue nodules on the lateral peritoneal surfaces or in the ligaments and mesenteries of the abdomen on CT and as medium signal intensity nodules on MRI.²⁴ Omental implants appear as discrete nodules or as conglomerate soft tissue masses (“omental cake”) beneath the anterior abdominal wall. They have a soft tissue

attenuation on CT (Fig. 59-15) and a medium signal intensity on MRI. Peritoneal and omental implants may enhance after IV contrast medium administration.

Other Adnexal Masses

Adnexal Torsion

Adnexal torsion is most commonly encountered after menarche. Patients present with acute or recurrent pelvic pain. Torsion results from rotation of the ovary or fallopian tube on its vascular pedicle, which causes compromise of lymphatic, venous, and arterial flow, and, ultimately, infarction. Torsion can occur in the presence of normal adnexa or in association with an underlying mass, most often a teratoma or ovarian cyst, which acts as a fulcrum. The diagnosis usually is suggested by ultrasonography,⁶⁴ but CT or MRI may be useful when a sonogram is indeterminate.

Figure 59-15. Mucinous ovarian carcinoma. *A*, Contrast-enhanced CT scan of a 14-year-old girl with abdominal distention and weight loss shows a complex cystic and solid mass behind the bladder (*BL*). The tumor has invaded the rectum (*open arrows*) and extended into the parametrial fat. *B*, At a more superior level, there is a soft tissue omental mass (“omental cake”) anterior to the liver and the mesenteric implants (*asterisks*).

On both CT and MRI, the edematous and usually hemorrhagic ovary is enlarged and may contain multiple, peripheral cystic structures that represent dilated follicles⁵ (Fig. 59-16). The involved ovary also may assume a mid-line position, either behind the bladder or cephalad to the uterus. Other findings include engorgement of blood vessels on the affected side, a thickened fallopian tube with hemorrhage, a small amount of ascites, obliteration of the pelvic fat planes, and an underlying cyst or tumor.^{23, 34} On MRI, the enlarged ovary usually demonstrates a high signal intensity on T1-weighted and T2-weighted images related to the presence of subacute hemorrhage and edema.³⁴ Viable ovarian tissue demonstrates some degree of enhancement on CT and MRI. The lack of enhancement of mural nodules or septa appears to be diagnostic of infarction.³⁴

Tubo-ovarian Abscess

Pelvic inflammatory disease affects girls of reproductive age and is usually due to *Neisseria gonorrhoeae* or *Chlamydia trachomatis*.²⁶ The inflammatory process begins in the vagina and cervix and then ascends to the endometrium and fallopian tubes, where it can spread to the ovaries, parametrium, and peritoneal cavity. The diagnosis is usually made clinically. Sonography is used to identify complications such as pyosalpinx, tubo-ovarian abscess, and cul-de-sac abscess and to assess the response to treatment. CT has a role in evaluating the extent of adnexal and peritoneal abscesses.

The CT appearance of an tubo-ovarian abscess is a round, thick-walled, fluid density mass in an adnexal location^{18, 74} (Fig. 59-17). Internal septations are common, and

Figure 59-16. Adnexal torsion in a 14-year-old girl with acute pelvic pain suspected to be caused by appendicitis. Contrast-enhanced CT shows an enlarged, nonenhancing mass of soft tissue density posterior to the urinary bladder (BL), corresponding to the left ovary. The low-attenuation areas (arrows) within the mass represent dilated follicles. An infarcted left ovary was confirmed surgically. S, sigmoid colon.

Figure 59-17. Pelvic inflammatory disease. Contrast-enhanced CT scan in a 17-year-old girl reveals a dilated right fallopian tube consistent with pyosalpinx (P), a round fluid-filled mass in the left adnexal region consistent with a tubo-ovarian abscess (T), and two pelvic abscesses (asterisks). Both lesions were confirmed surgically. The pelvic fat planes are obliterated. U, uterus.

air or an air-liquid level also may be noted. Pyosalpinx should be considered when a tubular fluid-filled adnexal mass is seen⁷⁴ (see Fig. 59-17). Loss of the fat planes that interface with the uterus, uretersacral ligament thickening, increased density in the pelvic fat, narrowing or irregularity of the rectosigmoid colon, bilateral or unilateral hydronephrosis and hydroureter, and lymphadenopathy are additional evidence for pelvic inflammatory disease.⁷⁴ In selected patients, CT may be used to guide percutaneous drainage of pelvic abscesses.

MRI is not usually indicated for the evaluation of tubo-ovarian abscess.

Prostate and Vagina

Rhabdomyosarcoma is the most common tumor of the genitourinary tract in children, accounting for 5% to 15% of all malignant solid tumors in patients younger than 15 years.^{38, 73} The median age of presentation of children with rhabdomyosarcoma is approximately 7 years.² The tumor has a bimodal age distribution, with the first peak occurring between 2 and 6 years of age and the second peak occurring between 14 and 18 years of age. The embryonal and botryoid subtypes are the predominant histologic subtypes in the genitourinary tract.

In the genitourinary tract, rhabdomyosarcoma can arise in the prostate, bladder, and vagina. Most patients with prostatic or bladder rhabdomyosarcoma present with signs of urinary retention. Females with gynecologic rhabdomyosarcoma come to clinical attention because of vaginal bleeding or a mass that prolapses into the introitus or onto the perineum. Rhabdomyosarcoma spreads via direct extension to contiguous structures or via hematogenous or lymphatic dissemination to lymph nodes, lungs, bone, bone marrow, or liver.^{2, 38, 50, 73} Between 10% and 20% of all

patients with rhabdomyosarcoma have metastases at the time of diagnosis. The overall 3-year survival rate is between 73% and 89%.²

Whenever possible, surgical excision is the initial treatment of choice. In patients with bulky nonresectable tumor, the initial treatment is chemotherapy followed by excision of residual disease. Radiation is added if there is still residual tumor. The goal of treatment is to minimize radical surgery and to preserve the major pelvic organs.

Imaging Findings

On CT scans, prostatic rhabdomyosarcoma is manifested as a bulky soft tissue mass that may elevate the bladder base and elongate the prostatic urethra (Fig. 59–18A). Vaginal rhabdomyosarcoma results in a soft tissue mass that enlarges the vaginal lumen^{3, 69} (Fig. 59–19). Secondary findings include uterine enlargement and fluid collections in the endometrial cavity when there is obstruction of the

Figure 59–18. Prostatic rhabdomyosarcoma in a 3-year-old boy with urinary retention. A, CT scan shows an enlarged prostate gland (P) between the rectum (R) and the bladder. The planes between the mass and obturator internus muscles (pelvic side walls) are obliterated. *Open arrow* indicates bladder catheter. Coronal T1-weighted (B) (400/15) and T2-weighted fat-saturated (C) (TR 2500/TE 90/180 degrees) images show a large prostatic mass (P) extending laterally to the pelvic side walls. There are enlarged iliac lymph nodes (*arrows*). Invasion of pelvic side walls and lymph nodes was confirmed at surgery.

Figure 59-19. Vaginal rhabdomyosarcoma in a 13-year-old girl with vaginal bleeding. CT scan shows a bulky, soft tissue mass (M) that expands the vagina and infiltrates the pelvic fat (arrowheads).

cervix by the tumor. Both prostatic and vaginal tumors may invade the bladder base or obstruct the ureters, leading to hydronephrosis.

On MRI, rhabdomyosarcoma demonstrates a low signal intensity on T1-weighted sequences and a high signal intensity on T2-weighted MRI images²¹ (Fig. 59-18B and C). Tumor heterogeneity secondary to necrosis and calcification are common. The tumor typically shows enhancement at MRI and CT after IV contrast medium administration.

The presence of fat planes between the neoplasm and adjacent structures militates against gross invasion, but the absence of fat planes may be normal or due to adherence or invasion. When the loss of fat planes is associated with an eccentric soft tissue mass, a confident diagnosis of extrvaginal or prostatic extension can be made. CT is useful in determining the extent of both regional and retroperitoneal lymph node enlargement and is the study of choice for the detection of pulmonary metastases. Lymphadenopathy has a spectrum of appearances, ranging from small discrete nodules to large conglomerate masses (Fig. 59-18C).

Other Vaginal and Uterine Neoplasms

Adenocarcinoma is a rare neoplasm of the vagina in childhood. The imaging features are similar to those of rhabdomyosarcoma.

Gestational trophoblastic disease can be a cause of an intrauterine mass in an adolescent girl. It represents a spectrum of tumors varying from the benign hydatidiform mole to the more malignant invasive mole and choriocarcinoma.^{27, 54, 71} The clinical features of trophoblastic disease are vaginal bleeding and elevated levels of serum human chorionic gonadotrophin.

CT and MRI are more useful than sonography in the evaluation of molar disease by better defining tumor extent. On CT, the uterus often is enlarged and shows heterogeneous contrast enhancement with central areas of lower

attenuation or hypoattenuating foci in the myometrium.^{27, 54, 71} On MRI, the trophoblastic neoplasm appears as a heterogeneous mass of low signal intensity on T1-weighted images and of high signal intensity on T2-weighted images.^{27, 71} Numerous cystic spaces are usually present within the mass. Other findings on CT and MRI examinations include a gestational sac, with or without a small fetal pole or immature fetus; tortuous dilated parametrial vessels; and enlarged ovaries that contain multiple theca-lutein cysts. Local invasion is suggested by the presence of parametrial extension. Distant metastases to the liver and lung are seen in *choriocarcinoma*.

Urinary Bladder

Bladder Neoplasms

Malignant Tumors

Rhabdomyosarcoma is the most common bladder tumor in childhood. The pathology and staging systems for rhabdomyosarcoma are similar to those described for vaginal and prostatic rhabdomyosarcoma. Symptoms of bladder rhabdomyosarcoma include a palpable pelvic mass, hematuria, increased frequency, and urinary retention.⁷³

On CT and MRI, bladder rhabdomyosarcoma appears as a sessile or polypoid soft tissue mass that deforms the bladder base. It often projects into the bladder lumen (botryoid, or "bunch of grapes" appearance). Central necrosis and hemorrhage are other common findings. With MRI, rhabdomyosarcoma shows low signal intensity on T1-weighted images and intermediate or high signal intensity on T2-weighted images. The tumor enhances after the IV administration of iodinated contrast medium or Gd-chelate compounds. Transitional cell carcinoma and leiomyosarcoma are rare bladder neoplasms in childhood. On CT and MRI, they produce focal or diffuse wall thickening or a sessile or polypoid mass.

Benign Tumors

Hemangioma, neurofibroma, pheochromocytoma, and leiomyoma of the bladder are rare neoplasms of the urinary bladder. In general, the CT and MRI features of these tumors are similar and include a sessile or polypoid mass that arises within the bladder wall and projects into the bladder lumen. If the tumor shows intense contrast enhancement, the diagnosis of hemangioma and pheochromocytoma should be considered. Tumor distribution along the neurovascular bundles is a finding of neurofibromatosis.

Urachal Anomalies

Embryologically, the anterior bladder wall and umbilicus communicate with each other via a tubular channel (i.e., the urachus). This channel closes before birth. Failed obliteration of the urachal lumen results in four major types of anomalies:

1. The patent urachus, a persistent fistula between the bladder and umbilicus.
2. The urachal sinus, persistence of the urachus at its umbilical end.

Figure 59–20. Urachal cyst. Contrast-enhanced CT scan shows a round, midline fluid-filled cyst (C) with thin, smooth walls just beneath the rectus abdominis muscles. The cyst did not communicate with either the bladder or the umbilicus.

3. The urachal diverticulum, persistence of the urachus at its bladder end.
4. The urachal cyst, an encapsulation of fluid within a portion of the urachus that is closed at both the cranial and caudal ends.

The persistent urachus and the urachal sinus are small-caliber tubular structures that are best evaluated with fistulography.⁴⁷ The urachal cyst and diverticulum are closed fluid-filled spaces that can be easily identified with sonography and CT.

On CT, the urachal diverticulum has a wide communication with the bladder dome and empties when the bladder

is emptied. The urachal cyst appears as a midline thin-walled, fluid-filled mass beneath the rectus abdominis muscle (Fig. 59–20). Increased density or heterogeneous fluid contents and cyst wall thickening may be seen with infection (pyourachus) or hemorrhage. Additional findings of pyourachus include bladder wall thickening, increased attenuation of the subcutaneous or mesenteric fat, rectus muscle thickening (Fig. 59–21), intraperitoneal abscess, and a small amount of ascites.²⁹

Other Pelvic Masses

Pelvic lymph node enlargement, abscess, hematoma, and urinoma are additional causes of a pelvic mass. CT can help establish the true nature of these abnormalities when sonography is indeterminate or suboptimal because of abundant intestinal gas, obesity, or overlying dressings or drainage tubes that impede sound transmission. MRI does not have a major role in evaluation of these lesions.

Pelvic lymph nodes are found along the course of the internal and external iliac veins and the femoral veins. The CT appearance of lymphadenopathy varies from a small number of discretely enlarged lymph nodes to a large conglomerate mass, in which individual nodes are no longer recognizable, obscuring the contours of normal surrounding structures (Fig. 59–22).

A mature abscess usually has a soft tissue rim that enhances after IV contrast medium administration and a fluid-filled center that may contain fluid or fluid mixed with gas, in the form of either small bubbles or an air-fluid level. The diagnosis of an abscess can be made with confidence if gas bubbles are demonstrated within an extraintestinal mass. In the absence of gas bubbles, an abscess may be indistinguishable from a urinoma or seroma. The latter masses should be considered when CT scans show a near-water-attenuation mass with thin or

Figure 59–21. Pyourachus on serial CT scans. A, CT scan just below the level of the umbilicus shows a thickened fistulous tract (arrowhead) between the anterior abdominal wall and the rectus abdominis muscles. B, A more inferior CT scan shows inflammatory infiltration of the abdominal wall as well as a large heterogeneous midline mass deep to the rectus muscles.

Figure 59-22. Lymphadenopathy secondary to Hodgkin's disease in a 13-year-old girl. Enlarged pelvic lymph nodes (N) cause compression and displacement of the urinary bladder (BL).

barely perceptible walls. Correlation with clinical history and physical examination and sometimes biopsy of the lesion will be required for diagnosis.

On CT, a hematoma appears as an abnormal soft-tissue mass, enlarging, obliterating, or displacing normal structures. The location and attenuation characteristics depend on the source of the hemorrhage and the age of the extravasated blood. Acute hematoma has an attenuation value that is equal to or greater than that of pelvic muscle, due to the high hemoglobin content.⁶⁸ As the hematoma matures, the red blood cells lyse and the attenuation value decreases. A chronic hematoma appears as a well-circumscribed, low-attenuation mass with a higher attenuation rim.

Presacral Tumors

Sacroccygeal Teratomas

Sacroccygeal teratomas are the most common tumor of the presacral space in children.¹² Four types of sacroccygeal teratomas have been described based on the relative amounts of internal and external tumor^{13, 72}:

Type I, predominantly external (47%)

Type II, external and intrapelvic (34%)

Type III, external, pelvic, and abdominal (9%)

Type IV, purely presacral (10%)

More than 90% of sacroccygeal teratomas are detected in the neonatal period and present as large soft-tissue masses in the gluteal region. The diagnosis is often delayed if the tumors are small and confined to the presacral area. These latter patients usually present in later childhood or adolescence with a history of chronic constipation. The incidence of malignant components varies with the extent of the tumor (38% in type IV versus 8% in type I) and patient age at diagnosis. The older the patient at the time of diagnosis, the greater the likelihood of malignant

transformation in the tumor. About 20% of all sacroccygeal teratomas exhibit malignant elements.^{13, 72} Malignant tumors metastasize to lung and occasionally to liver or lymph nodes.

Imaging Findings

The diagnosis of sacroccygeal teratoma is usually obvious when a patient presents with a large pelvic or gluteal mass, but imaging is warranted to determine the full extent of tumor. Both CT and MRI can be used to characterize and stage sacroccygeal teratomas. Like teratomas elsewhere, benign sacroccygeal teratomas are mainly fluid-filled^{33, 72} and have an attenuation value equal to or slightly above that of water. They contain less than 50% solid elements, in the form of fat, calcification, bone, or teeth. The solid components may appear as a rounded mass that protrudes from a cyst wall, as a bridge or band that crosses the cyst, or as a thickened segment of cyst wall. Calcifications may be amorphous, punctate, or spiculated, or they may resemble bone formation.⁷² Although sacroccygeal teratomas arise from the coccyx, abnormalities of the spine are uncommon.

Benign teratomas typically appear as low-signal-intensity masses on T1-weighted images and as high-signal-intensity masses on T2-weighted images, reflecting their aqueous or sebaceous contents. The signal intensity can be higher than that of simple fluid on T1-weighted images when the cyst contents are proteinaceous or hemorrhagic (Fig. 59-23). Fat appears as a high-signal-intensity focus on T1-weighted and T2-weighted images; calcification, bone, and hair appear as low-signal-intensity foci on both T1-weighted and T2-weighted images.

Similar to teratomas elsewhere in the body, malignant teratomas are predominantly solid masses^{33, 51, 72} (Fig. 59-24). Calcifications, common in benign teratomas, are less frequent in the malignant forms. Signs of local extension include intraspinal involvement, soft tissue stranding, or an eccentric soft tissue mass. The tumor metastasizes to the lung and occasionally to the liver or retroperitoneal lymph nodes.

CT suffices for the diagnosis and determination of the extent of benign sacroccygeal tumors. Because of its superb soft tissue contrast, MRI is the imaging study of choice to determine the extent of a malignant sacroccygeal teratoma. MRI is superior to CT in the detection of invasion of pelvic soft tissue structures and in the identification of intraspinal involvement.³² After treatment, malignant sacroccygeal tumors may regress entirely, leave a small fibrotic mass, or may convert to a mature teratoma.¹⁴

Other Presacral Masses

Neurogenic tumors, including neuroblastoma and neurofibroma, anterior meningocele, rectal duplication cyst, and lymphoma, are other causes of presacral masses in childhood.

Approximately 5% of neuroblastomas arise in the pelvis. On CT and MRI, pelvic neuroblastomas appear as heterogeneous soft tissue masses with areas of necrosis and amorphous, coarse calcifications (Fig. 59-25). Benign neu-

Figure 59-23. Benign sacrococcygeal teratoma. *A*, T1-weighted (500/16) image shows a large pelvic mass with external and presacral components. The presacral components (*curved arrows*) have a high signal intensity similar to that of subcutaneous fat. The larger posterior portion of the mass (*arrowheads*) extending into the gluteal muscles has an intermediate signal intensity. *B*, On a T2-weighted (2500/90) image, the presacral mass again has an intensity equal to that of subcutaneous fat. The extrapelvic portion of the tumor has a signal intensity higher than that of fat, consistent with fluid. A predominantly cystic mass with fat and few soft tissue elements is characteristic of a benign teratoma. (Courtesy of Andrew Landes, M.D., Hollywood, Fla.)

Figure 59-24. Malignant presacral teratoma in a newborn girl with a gluteal mass. CT scan demonstrates a large heterogeneous mass of soft tissue density displacing the gas-filled rectum (*arrowhead*) anteriorly. *E*, lower extremities.

Figure 59-25. Presacral neuroblastoma. Nonenhanced CT shows a large mass (*M*) of soft tissue attenuation anterior to the sacrum (*S*) and posterior to the bladder (*BL*). The tumor has invaded the right sacroiliac joint and the right iliac wing.

Figure 59-26. Neurofibromatosis. A, CT scan of a 18-year-old girl shows low-attenuation masses (M) with a density less than that of myometrium and muscle in the left hemipelvis. BL, bladder. Open arrow indicates the left ovary. B, Transaxial T2-weighted fast spin-echo (TR 3000/TE 54/180 degrees) image shows high-signal-intensity neurofibromas in the left paraspinal area and involving the sacral foramen.

rofibromas usually have a homogeneous appearance and a low attenuation value on CT that is slightly higher than that of water but much lower than that of paraspinal muscle, a low or intermediate signal intensity on T1-weighted images, and a high signal intensity on T2-weighted images (Fig. 59-26). The low-attenuation value in benign lesions may reflect the presence of cystic degeneration, hypocellularity, or xanthomatous (fatty) tissue. Because of their neural origin, neuroblastomas and neurofibromas can invade the spinal canal. MRI is superior to CT in delineating the extent of intraspinal disease.

The anterior meningocele herniates through a congenital defect in the vertebral body. It is most common in the sacral region and at the lumbosacral junction. When the contents of the herniated sac contain neural elements in addition to meninges and cerebrospinal fluid, the mass is termed a *myelomeningocele*; when fat and cerebrospinal fluid are present, the mass is termed a *lipomeningocele*.

The diagnosis of an anterior meningocele or myelomeningocele can be strongly suspected on conventional radiographs when a presacral mass is seen in association with a scimitar- or crescent-shaped sacrum. CT can demonstrate the fluid-filled sac of the meningocele, the bony defect in the lumbar vertebra or sacrum, the low-attenuation fatty elements of a lipomeningocele, and the relationship of the lesion to the spine and other structures of the pelvic cavity. Although the diagnosis can be made with CT, the soft tissue contents of the herniated spinal sac, especially the presence of a tethered cord and the communication between the meningocele and the thecal sac, are demonstrated best with MRI.

Rectal duplication cysts account for about 10% of all gastrointestinal duplications.³⁹ They usually appear as thin-walled, fluid-filled, round or oval masses attached to the

rectum (Fig. 59-27). The attenuation value and MR signal characteristics of the cyst contents are usually similar to those of water. However, the attenuation value and signal intensity on T1-weighted images can be higher if the cyst contains blood or mucinous material. On occasion, duplication cysts communicate with the true colon.

Lymphomas and chordomas are rare presacral tumors in children. On CT and MRI, presacral lymphoma appears as a homogeneous soft tissue mass. CT and MRI examination of chordomas reveals a soft tissue mass with amorphous cartilaginous calcifications. Chordomas typically produce destruction of the sacrum and coccyx.

Figure 59-27. Rectal duplication cyst in a 4-year-old girl with chronic constipation. A nonenhanced CT scan shows a well-circumscribed ovoid cyst (C) of water attenuation in the presacral region displacing the rectum (R) anteriorly.

Localization of Undescended Testes

The prevalence of undescended testis (*cryptorchidism*) is 3.5% at birth and decreases to 0.8% by 1 year, because many testes descend spontaneously.²² Identification of an undescended testis or cryptorchidism is important because of the increased incidence of infertility and neoplasm if the testis remains undescended. Early surgery, either orchiopexy in younger patients or orchiectomy in postpubertal patients, minimizes but does not eliminate those risks.^{22, 49}

The testis develops from the embryonic gonad, which arises ventral to the mesonephric ridge. It migrates from its abdominal position to the scrotal sac during the late portion of gestation.⁴⁹ Arrest of this migratory process produces an ectopically positioned testis. Ultrasonography can reliably detect an undescended testis when it is intracanalicular, which occurs in about 90% of cases. Ultrasonography, however, is not usually reliable in detecting the undescended testis located higher in the pelvis or in the abdomen. If sonographic findings are equivocal or negative and preoperative localization of the testis is desired, either CT or MRI can be performed. A disadvantage of MRI in children, compared with CT, is the lack of a contrast agent to opacify bowel loops, which makes detection of the atrophic testis more difficult.

The CT features of an undescended testis are an oval, soft tissue mass located anywhere along the pathway of testicular descent, from the lower pole of the kidney down to the external inguinal ring.^{22, 35, 36} The undescended testis

is usually smaller than the normally descended testis. The demonstration of an undescended testis that is unusually large or heterogeneous should suggest malignant transformation.³⁷ The accuracy of CT for localization of nonpalpable testes exceeds 90%.^{35, 75, 76} Unless it is atrophic or ischemic, the undescended testis has an intermediate signal intensity equal to that of muscle on T1-weighted images (Fig. 59–28) and higher than that of subcutaneous fat on T2-weighted images. Undescended testes that are atrophic or ischemic may have a signal intensity lower than that of the normal testis.

Musculoskeletal System

Peter J. Strouse

Tumors of Bone

Imaging of pediatric bone tumors begins with conventional radiography. Radiographs may characterize a lesion such that a specific diagnosis can be made or a narrow differential diagnosis constructed. Radiographs serve to guide the planning of subsequent magnetic resonance imaging (MRI) and computed tomography (CT) examinations.

MRI delineates the intramedullary extent, cortical violation, and extraosseous extension of bone tumors. In children, MRI is the best method to demonstrate the relationship of a tumor to the growth plate, epiphysis, and articular surface. A drawback of MRI is its inability to demonstrate calcification. Tumor matrix and periosteal new bone formation are thus not well assessed. The MRI examination should always be interpreted with correlative radiographs, which provide information on tumor matrix, periosteal new bone formation, and lesion margins. MR images should also be assessed for metastases, including skip lesions and lymph node disease. MRI demonstration of neurovascular encasement may alter therapy.

The approach to an MRI protocol for a bone tumor should be based on information obtained from preceding history, physical examination, and plain radiographs. If a nonaggressive process is suspected, the examination can be targeted to the area of interest from the start. If the process is thought to be aggressive, such as osteosarcoma or Ewing's sarcoma, it is wise to start with a broader field of view (Fig. 60-1). Imaging is often started in a body coil to image the full length of the affected bone. Coronal T1-weighted images and sagittal inversion recovery images suffice. Once skip lesions have been excluded and the longitudinal extent of the tumor is defined, a smaller coil is used to target the area of interest with higher resolution.

With their focus on the tumor, axial T1-weighted images with and without fat saturation, and axial T2-weighted images are obtained. After the administration of gadolinium (0.1 mmol/kg), axial and coronal T1-weighted fat saturation images are obtained. Imaging planes may vary on the basis of tumor location. Pregadolinium T1-weighted fat saturation images can be omitted to shorten examination time, but they are often helpful in characterizing and defining the extent of enhancement on the postgadolinium images. If there is a possibility of vascular encasement or if the tumor itself is potentially vascular in nature, time-of-flight images can be added.

The enhancement pattern of musculoskeletal neoplasms is an area of active research. Several investigators have studied temporal enhancement patterns as a method of

distinguishing different types of tumors, differentiating tumor from peritumoral edema, assessing tumor response to therapy, and identifying viable residual tumor.^{21, 24, 52, 53}

Malignant Bone Tumors

Osteosarcoma

Any sarcoma that produces bone is, by definition, an osteosarcoma. Osteosarcoma is the most common malignant bone tumor of childhood. It most often presents in the second decade of life but is occasionally seen in children younger than 10 years of age and not infrequently in the young adult. Patients usually present with pain or a painful mass. Although osteosarcoma can develop in any bone, most of the tumors are seen in metaphyses of long bones.

On plain radiographs, osteosarcomas are varied in appearance. Most commonly, radiographs show an aggressive lytic lesion with osteoid production, aggressive periosteal reaction ("hair-on-end," "onion-skin," Codman's triangle), and a soft tissue mass. Less commonly, lesions are predominantly sclerotic. Rarely, an osteosarcoma produces a well-defined, lytic lesion that might be mistaken for a nonaggressive lesion. Plain radiographs often allow the specific diagnosis of osteosarcoma.

MRI is performed in patients with suspected osteosarcoma to confirm the diagnosis and, more often, to assess the extent of disease (see Fig. 60-1).^{28, 69, 70, 72, 77} Like most neoplasms, osteosarcoma is of low signal intensity on T1-weighted images and of high signal intensity on T2-weighted images. Areas of osteoid production may be seen as low signal (Fig. 60-2). MRI shows the extent of intramedullary and extraosseous tumor. Edema is seen at the margins of the tumor, within bone and adjacent soft tissues. A sharp margin of the lesion allows its differentiation from an inflammatory condition (i.e., osteomyelitis). The mass enhances with gadolinium administration. There may be extensive areas of necrosis.

Occasionally, fluid-fluid levels are seen. These are common with telangiectatic osteosarcoma, or they may indicate a secondary aneurysmal bone cyst. The presence of a fluid-fluid level is not indicative of a benign lesion.⁹²

Parosteal Osteosarcoma

Parosteal osteosarcoma presents most often in young adults but occasionally in the second decade. The dorsal surface of the distal femur is a common location. Parosteal osteosarcomas are often heavily ossified for their size. A cleavage plane may be seen between the tumor and the

Figure 60-1. Osteosarcoma of the distal femur in a 13-year-old girl.

A, A plain radiograph is diagnostic. An aggressive lesion is seen within the distal femoral metaphysis. The mass effect can be visualized medially (*arrows*), with faint osteoid production and periosteal new bone (*arrowheads*).

B, The MRI examination begins in the body coil with T1-weighted images (TR = 300 msec, TE = 14 msec) covering the entire femur to exclude skip lesions and determine the proximal extent of tumor (*arrows*). Subsequently, an extremity coil is used to better define the tumor.

C, Coronal inversion recovery image (TR = 4000 msec, TE = 30 msec, TI = 165 msec) shows the tumor (T) as having a high signal within the distal femoral metaphysis. A portion of the soft tissue mass, which is of fluid signal intensity due to necrosis, is seen medially (*long arrows*). Note a small extension of the tumor across the distal femoral growth plate into the epiphysis (*small arrow*).

D, Postgadolinium axial T1-weighted image (TR = 716 msec, TE = 14 msec) with fat saturation shows the extent of the soft tissue mass (*arrows*). The *curved arrow* marks a tract from the preceding biopsy. The patient eventually underwent a limb salvage procedure with a total knee arthroplasty with a long-stem femoral component.

underlying cortex.⁶³ CT helps to differentiate parosteal osteosarcoma from osteochondroma and myositis ossificans (Fig. 60-3).³⁹ MRI better defines the degree of intraosseous extension.

Periosteal Osteosarcoma

Periosteal osteosarcoma is extremely rare, particularly in childhood. These lesions are frequently diaphyseal and involve the lower extremities. The tumor is closely apposed

to the cortex of the underlying bone. A juxtacortical mass with hair-on-end periosteal new bone is characteristic.⁶³

Ewing's Sarcoma

Ewing's sarcoma is the second most common malignant bone tumor of childhood. It is rare in infancy but otherwise presents throughout childhood and occasionally in early adulthood. As with osteosarcoma, the most common presentations are pain or a painful mass. In younger children,

Figure 60-2. Osteosarcoma in a 15-year-old boy. Postgadolinium axial T1-weighted image (TR = 550 msec, TE = 8 msec) with fat saturation shows enhancing soft tissue of an osteosarcoma replacing the proximal tibial metaphysis. The cortex is largely destroyed. An area of low signal intensity (arrows) represents osteoid formation. F, fibula.

Ewing's sarcoma most commonly presents in the diaphyses of the long bones. In older children, Ewing's sarcoma tends to occur in bones of the axial skeleton, such as within the pelvis. Ewing's sarcoma is an aggressive neoplasm. Metastatic disease is common at presentation.

On plain radiographs, Ewing's sarcoma is usually seen

Figure 60-3. Parosteal osteosarcoma of the distal femur in a 15-year-old girl. CT shows central ossification within the lesion and involvement of the medullary space (arrows).

Figure 60-4. Ewing's sarcoma of the distal femur in a 15-year-old boy. The CT image at the bone window shows characteristic "onion skin" periosteal new bone formation.

as a permeative lesion of bone. The tumor does not produce osteoid matrix; however, there may be abundant periosteal new bone formation. Onion-skin periosteal new bone is characteristic (Fig. 60-4). The extraosseous soft tissue component may be large, particularly with pelvic or chest wall tumors. Rarely, Ewing's sarcoma can arise primarily within soft tissue ("extraosseous"). The radiographic findings in Ewing's sarcoma are less specific than in osteosarcoma. In particular, osteomyelitis can mimic Ewing's sarcoma in the long bones. The clinical presentations overlap as well. In the axial skeleton, other neoplasms, such as primitive neuroectodermal tumor (PNET) and rhabdomyosarcoma, mimic Ewing's sarcoma.

As with osteosarcoma, MRI shows the extent of neoplasm within the medullary space, extension through the cortex, and associated soft tissue mass (Figs. 60-5 and 60-6).^{28, 29} Peritumoral edema may render margins of the tumor indistinct on some imaging sequences. Usually, the tumor has well-defined margins on at least one sequence, which is often conventional T1-weighted, helping to differentiate it from infection.

Primitive Neuroectodermal Tumor

PNET can originate in bone or soft tissue. This aggressive tumor is seen throughout childhood. In the skeleton, PNET is seen as a destructive tumor with associated soft tissue mass, indistinguishable from Ewing's sarcoma (Fig. 60-7). Metastases are common at the time of presentation. PNET is most commonly seen in the pelvis and chest wall. Tumors at the latter location are known as *Askin's tumors*.

Lymphoma

Focal osseous involvement of lymphoma occurs in only a small percentage of pediatric patients with lymphoma. On radiographs and MRI, lymphoma in bone appears similar

Figure 60-5. Ewing's sarcoma of the distal femur in a 5-year-old girl. Postgadolinium axial T1-weighted image (TR = 550 msec, TE = 11 msec) with fat saturation shows an eccentric mass enveloping the distal femur. Anterior thigh musculature is displaced. Enhancing tumor is also seen in the medullary space. The neurovascular bundle (arrow) is not involved.

Figure 60-7. Primitive neuroectodermal tumor arising from the right hemipelvis in a 14-year-old boy. Postgadolinium coronal T1-weighted image (TR = 700 msec, TE = 14 msec) with fat saturation shows the mass (M) to extend into proximal thigh and to displace the bladder (B). The medial right acetabulum is destroyed. Metastatic lesions can be seen within the lower spine, left ilium, and left proximal femur (arrows).

Figure 60-6. Ewing's sarcoma of the cuboid bone in an 8-year-old boy. A, Radiograph shows a lytic expansile lesion of the cuboid bone (C). B, Postgadolinium axial T1-weighted image (TR = 716 msec, TE = 14 msec) with fat saturation shows enhancing soft tissue replacing the cuboid (C). Areas of necrosis are seen as low signal intensity. The cortex of the cuboid is partially destroyed. Enhancement is seen within adjacent soft tissues as a result of peritumoral edema. E, vitamin E capsule.

to other malignant lesions. Bone destruction, aggressive periosteal new bone, and soft tissue mass are seen along with a permeative pattern of destruction. Both long bones and flat bones are affected. Involvement of vertebral bodies is not uncommon.

Giant Cell Tumor

Giant cell tumors are not encountered until late in childhood, after the growth plates are fused. This tumor is characterized on plain radiographs as a well-defined lesion, bridging the growth plate and abutting the articular surface. Fluid-fluid levels may be seen on CT and MR. Typically, no extrasosseous soft tissue component is seen.

Leukemia

Leukemia can produce focal destructive masses anywhere in the skeleton. More commonly, lesions are confined to the metaphyses of growing bones. Early in the disease, leukemic infiltration is confined to within the medullary space. If treatment is delayed, osseous destruction can progress to the extent of pathologic fracture. Large extrasosseous soft tissue masses may appear identical to osteosarcoma by MRI (Fig. 60–8). Involvement of multiple bones suggests the diagnosis. Plain films may show characteristic lucent metaphyseal bands.

Metastases

Metastases to bone are much less common in children than in adults. Pediatric neoplasms metastasizing to bone

Figure 60–8. Focal distal left femoral mass due to acute lymphocytic leukemia in a 4-year-old girl. The patient initially presented with distal thigh pain and was thought to have a primary bone neoplasm of the distal femur. Axial T1-weighted image (TR = 689 msec, TE = 13 msec) shows a circumferential soft tissue mass encasing the distal femur. The underlying femoral cortex is nearly absent (arrows). Lesser abnormality was present within the other metaphyses of both knees. Plain films showed destructive changes in the distal left femur with characteristic leukemic lucent bands in the other metaphyses.

Figure 60–9. Unicameral bone cyst of the left proximal femur and resultant pathologic fracture in a 3-year-old girl. The lesion is mildly expansile and thins the overlying cortex. Note the fallen fragment within the cyst from the fracture (arrow).

include neuroblastoma, PNET, Wilms' tumor, hepatoblastoma, and osteosarcoma. Neuroblastoma is most common. A metastasis can mimic a primary neoplasm of bone on radiography or MRI.

Benign Bone Tumors

Plain films often suffice in the characterization of nonaggressive, benign bone lesions. MRI is thus indicated less often for these lesions than it is for aggressive, malignant lesions. CT is occasionally helpful in characterizing benign lesions on the basis of their effect on the host bone.

Simple (Unicameral) Bone Cyst

Simple bone cysts are seen as well-defined oval metaphyseal lesions without aggressive characteristics on plain radiographs. Neither MRI nor CT is indicated unless atypical features suggest a more aggressive lesion. Not infrequently, bone cysts present as a result of a pathologic fracture. CT may be helpful in demonstrating a "fallen fragment," indicative of a simple bone cyst (Fig. 60–9).

Aneurysmal Bone Cyst

Aneurysmal bone cysts are well-defined, multiloculated, expansile lesions. The overlying cortex is thinned but present. These cysts can occur anywhere within the skeleton, although locations in the long bones are most common. Presentation is usually the result of a pathologic fracture or pain. A few aneurysmal bone cysts form secondary to underlying lesions, including malignancies such as osteosarcoma. Images must be carefully inspected for evidence of an underlying lesion. On MRI and CT, an aneurysmal bone cyst is seen as a multilocular lesion.^{4, 38} Larger loculi show fluid–fluid levels (Fig. 60–10).³⁸ Septations and margins of the lesion enhance. Any soft tissue component should raise suspicion for an underlying malignancy. Pathologic confirmation of benignity is recommended for all lesions.

Fibrous Cortical Defect/Nonossifying Fibroma

Fibrous cortical defects and nonossifying fibromas are very common benign lesions of bone whose appearance on

Figure 60-10. Aneurysmal bone cyst of the distal femur in a 10-year-old boy. Axial T2-weighted image (TR = 2500, TE = 95) without fat saturation shows multiple fluid-fluid levels within the lesion.

radiographs is diagnostic. These lesions are asymptomatic unless they are large enough to cause a pathologic fracture. Fibrous cortical defects are smaller than 2 cm, and nonossifying fibromas are larger than 2 cm. Atypical lesions may warrant evaluation with MRI or CT for characterization. Lesions are detected incidentally on studies performed for other indications. The lesions are metaphyseal in location, moving away from the growth plate with time and involuting by skeletal maturation.

On radiographs and CT, a well-defined cortical lesion with a sclerotic margin is seen.¹⁰⁰ On MRI, lesions are well defined, with a low signal intensity on T1-weighted images and a high signal intensity on T2-weighted images. No adjacent edema is seen. Radiographs should be reviewed or obtained for confirmation.

Osteochondroma

Osteochondroma (*exostosis*) is a nonaggressive, benign lesion with a characteristic radiographic appearance. The lesion is corticated with a medullary space contiguous with that of the underlying metaphyseal bone. Lesions may be sessile or pedunculated. Pedunculated lesions are directed away from the end of the bone. Most osteochondromas are asymptomatic unless they are located so as to cause stress irritation of an overlying muscle or tendon, or mass effect. Although malignant degeneration is rare, pain in a previously asymptomatic osteochondroma or growth after skeletal maturity should raise concern for malignant degeneration.

CT is occasionally performed to define the three-dimensional anatomy of an osteochondroma. On MRI, the cartilaginous cap parallels articular cartilage in signal intensity and is well defined (Fig. 60-11).^{43, 63} Irregularity or thickness greater than 2 cm should raise concern for malignancy.⁶³ Patients with the syndrome of multiple hereditary exostoses have numerous osteochondromas throughout the skeleton.

In patients with Trevor's disease (dysplasia epiphysealis

Figure 60-11. Osteochondroma of the proximal tibia in a 12-year-old boy. A vitamin E capsule (E) was placed on the palpable abnormality prior to scanning and overlies the lesion. The cartilaginous cap is well defined and of high signal intensity on this proton-density image (TR = 2700 msec, TE = 17 msec) with fat saturation.

hemimelica), osteochondroma-like lesions of the epiphyses develop. Classically, the lesions involve one side of the bone. Adjacent bones or joints within the same extremity may be involved. Deformity may interfere with bone growth and joint function. CT, MRI, and arthrography have been used to delineate the abnormality.

Enchondroma

Enchondromas are diagnosed infrequently in children. These lesions are well defined and typically metaphyseal in location. Punctate calcification ("arcs and rings") may be evident on plain radiography or CT. On MRI, lesions are well defined and of high signal intensity on cartilage sequences (Fig. 60-12). Irregularity, soft tissue mass, or clinical symptoms should raise concern for chondrosarcoma, which can have an imaging appearance very similar to that of enchondroma.³⁰

Osteoid Osteoma

Osteoid osteomas present throughout childhood and into early adulthood. The classic history is that of pain, particularly at night, relieved by aspirin. Most osteoid osteomas are cortical. The lesion produces sclerosis, cortical thickening, and exuberant smooth periosteal new bone. The osteoid osteoma is seen as a lucent nidus centered within the sclerotic region. A punctate opacity may be seen with the lucent nidus. The nidus may be identified by radiography; however, CT is performed to confirm the diagnosis and localize the nidus (Fig. 60-13).⁶⁰ At some institutions, curative biopsies are performed under CT guidance.⁹¹

Osteoid osteomas within the joints produce little reactive

Figure 60-12. Multiple enchondromatosis in a 12-year-old boy. Axial T2-weighted image (TR = 3500 msec, TE = 105 msec) shows the enchondromas as well-defined high-signal-intensity lesions (arrows) with no adjacent edema. The quadriceps tendon (Q) is medially displaced as a result of deformity of the distal femur (not illustrated).

bone.⁷⁸ Intramedullary osteoid osteomas also produce little periosteal new bone or cortical thickening. Intramedullary lesions may mimic osteosarcoma or stress fractures in their radiographic appearance. CT suggests the diagnosis by showing a radiolucent nidus within an area of medullary sclerosis.¹

On MRI, osteoid osteoma produces an amount of edema that is disproportionately large relative to the size of the lesion, thus simulating a more aggressive lesion (Fig. 60-14). Edema extends into the adjacent soft tissues. The nidus can occasionally be identified centrally within the lesion.¹ Correlation with plain radiographs is imperative.

Figure 60-13. Osteoid osteoma of the proximal tibia in an 8-year-old girl. A punctate sequestrum is seen within the lucent nidus (arrow). Note the diffuse cortical thickening. F, fibula.

Figure 60-14. Osteoid osteoma of the proximal femur in an 8-year-old boy. Postgadolinium axial T1-weighted image (TR = 750 msec, TE = 12 msec) with fat saturation shows the nidus at the inner margin of the medial cortex (arrow). Marked enhancement is seen within the adjacent medullary cavity and extraosseous soft tissues.

Chondroblastoma

Chondroblastoma most commonly presents in the second decade of life. These lesions may produce pain, typically localized near a joint because of the epiphyseal and apophyseal location of the lesions. Radiographically, a well-defined round lesion is identified within an epiphysis or apophysis. The lesion may abut the articular surface. MRI or CT can be performed to further characterize the lesion and delineate its relationship to the articular surface and growth plate (Fig. 60-15).^{71, 94} On CT, cartilaginous matrix may be evident. On MRI, the lesion is well defined and parallels cartilage in signal intensity. The differential diagnosis includes osteochondritis dissecans, epiphyseal osteomyelitis, and eosinophilic granuloma.

Fibrous Dysplasia

Fibrous dysplasia may present as a solitary lesion or as a multifocal abnormality. In McCune-Albright syndrome, children present with precocious puberty, café-au-lait spots, and polyostotic fibrous dysplasia. The radiographic and CT appearance of fibrous dysplasia is varied.⁴⁸ Focal lesions are well defined and expansile. A “ground glass” appearance of the medullary space may be seen (Fig. 60-16). On MRI, lesions vary in signal intensity on T2-weighted images.^{25, 97}

Langerhans' Cell Histiocytosis

Langerhans' cell histiocytosis represents a spectrum of abnormality, ranging from a solitary bone lesion to a dif-

Figure 60-15. Chondroblastoma of the greater trochanter of the femur in a 14-year-old boy. *A*, CT shows a relatively well defined lucent expansile lesion with a few punctate internal calcifications (*arrows*). *B*, Axial postgadolinium T1-weighted image (TR = 550 msec, TE = 18 msec) with fat saturation shows marked enhancement within the adjacent soft tissues as a result of irritation. The lesion (*arrows*) enhances minimally. A small bursa is evident (*curved arrow*).

fuse process with skeletal and visceral involvement. Solitary lesions are still commonly referred to as eosinophilic granuloma. Langerhans' cell histiocytosis can have virtually any radiographic appearance; however, lesions typically do not show markedly aggressive features. Classic

lesions are well defined on plain radiographs, with minimal sclerosis or periosteal reaction. Exceptions to this are common. Eosinophilic granuloma can affect any bone at any location, including the epiphyses. On MRI scans, lesions show a nonspecific low signal on T1-weighted images and a high signal on T2-weighted images, and they enhance briskly (Fig. 60-17).²⁷ There may be extraosseous extension of soft tissue.⁸⁶

Figure 60-16. Polyostotic fibrous dysplasia in a 12-year-old boy. A CT image through the right hip shows a spectrum of appearances including "ground glass" abnormality (*g*), lucent, expansile change with punctate calcification (*large arrows*), and smaller lucent lesions (*small arrows*). An intramedullary rod (*i*) is present.

Figure 60-17. Focal Langerhans' cell histiocytosis of the right ischium in a 3-year-old girl. Postgadolinium axial T1-weighted image (TR = 600 msec, TE = 18 msec) with fat saturation shows marked, but slightly inhomogeneous, enhancement within the lesion (*arrows*). The medial ischial cortex is destroyed.

Soft Tissue Masses

Imaging of soft tissue masses in children begins with radiography. Radiographs exclude the bony origin of the mass. The presence of calcification (e.g., phleboliths) or ossification (as in myositis ossificans) may suggest a particular diagnosis or may serve to guide subsequent imaging.

Most soft tissue tumors are similar in attenuation and enhancement to skeletal muscle and are thus poorly delineated by CT. Because of its greater tissue contrast and multiplanar capability, MRI is the preferred method for delineation of soft tissue tumors. The MRI imaging sequences used to evaluate soft tissue tumors are similar to the protocol previously outlined for bone tumors. Precontrast T1-weighted images with fat saturation are helpful in differentiating high signal caused by hemorrhage from that caused by enhancement. Time-of-flight images are helpful in assessing vascular soft tissue masses.

Malignant Soft Tissue Masses

Rhabdomyosarcoma

Rhabdomyosarcoma is the most common malignant soft tissue mass of childhood. It presents throughout childhood and may originate in any muscle. On T1-weighted images, the lesion is similar in signal intensity to skeletal muscle and is thus difficult to detect and define. On proton-density, T2-weighted, inversion recovery, and postgadolinium images, rhabdomyosarcoma shows increased signal intensity relative to muscle and is well visualized. Tumor margina-

tion varies. Rhabdomyosarcoma is indistinguishable from other malignant soft tissue masses. Lymph node metastases parallel the primary tumor in signal intensity on all sequences.

Synovial Sarcoma

Synovial sarcoma is a relatively uncommon soft tissue mass that arises from mesenchyme. In children, this tumor is most common in the second decade and usually arises near tendon sheaths, not joints. Calcifications may be present on plain radiographs, suggesting the diagnosis. MRI reveals a nonspecific soft tissue mass (Fig. 60–18).⁶⁵

Other Malignant Soft Tissue Masses

Liposarcoma, fibrosarcoma, angiosarcoma, and malignant fibrous histiocytoma are all extremely rare in childhood. Fibrosarcoma may be congenital.⁵⁷ Liposarcoma is seen as an aggressive mass containing both soft tissue and fatty components. Otherwise, these tumors have a nonspecific presentation and appearance.

Benign Soft Tissue Masses

Lipoma

Lipomas are relatively uncommon in children but the incidence increases with age. Lesions present as a painless lump or area of fullness. On CT or MRI, the lesion has a homogeneous appearance consistent with fat. No soft tissue component is seen.

Figure 60–18. Synovial sarcoma of the popliteal fossa in a 7-year-old girl. *A*, Postgadolinium axial T1-weighted image (TR = 500 msec, TE = 8 msec) with fat saturation shows a multilobular mass (M) abutting the posterior margin of the femur and partially encasing the neurovascular bundle (arrow). *B*, Coronal maximum intensity projection time-of-flight image (TR = 7.8 msec, TE = 2.4 msec, flip angle = 45 degrees) showing the three-dimensional relationship of the mass to the vasculature. Imaging was performed after gadolinium enhancement, which accounts for the increased signal intensity of the mass.

Lipoblastoma

Lipoblastoma is a rare neoplasm, typically presenting in children younger than 5 years of age. Although it is a benign tumor, lesions can be locally aggressive and may recur repeatedly if they are not completely excised.¹⁰ Some lesions reportedly mature to stable, benign lipomas. Both the extremities and the trunk can be affected. In most patients, the lesion is solitary. The term *lipoblastomatosis* refers to the presence of multiple lesions.¹⁰

The various appearances of lipoblastomas on CT and MRI correspond to their varied histologic features (Fig. 60–19).^{44, 49} Portions of the tumor with homogeneous fatty tissue on histologic examination have an appearance on CT and MRI that parallels normal body fat. Portions of the tumor with mucoid degeneration have an appearance on CT and MRI that is more congruent with soft tissue.

Fibromatous Lesions

A variety of fibromatous lesions may be seen in the pediatric age group. Lesions may be solitary or multifocal, and they may be indolent and nonaggressive or frankly aggressive.^{22, 59, 74} Aggressive lesions may be characterized as fibrosarcoma. Contrary to the common expectation that fibrous lesions are of low signal intensity on all sequences, fibromatous lesions of childhood may show high signal intensity on T2-weighted and inversion recovery images.^{22, 46, 59, 74} Margins may be well defined or infiltrative. Enhancement with gadolinium is variable (Fig. 60–20).

Neurofibroma

Neurofibromas may be solitary or multiple. Patients with neurofibromatosis may have multiple lesions or large

Figure 60–19. Lipoblastoma of the left supraclavicular soft tissues in a 17-month-old girl. Coronal T1-weighted image (TR = 550 msec, TE = 14 msec) shows a predominantly high-signal-intensity mass (M). The mass paralleled subcutaneous fat on all imaging sequences. An area of lower signal intensity (arrows) represents myxoid degeneration of a portion of the tumor.

Figure 60–20. Aggressive fibromatosis of the posterolateral abdominal wall musculature in a 12-year-old boy. Axial postgadolinium T1-weighted image (TR = 700 msec, TE = 10 msec) with fat saturation shows marked enhancement of the mass (M). Lesion margins are irregular. b, bowel; p, psoas muscle.

Figure 60–21. Neurofibromatosis in a 4-year-old boy. Coronal inversion recovery image (TR = 4000 msec, TE = 30 msec, TI = 150 msec) shows a large plexiform neurofibroma. The multilobular appearance, central low signal intensity with lobules (“target sign”) (arrows), and plexiform course of the mass following the expected anatomic location of a nerve and its branches are characteristic findings.

Figure 60-22. Hemangioma of the arm in a 2-year-old girl. Axial proton-density image (TR = 3700 msec, TE = 21 msec) with fat saturation shows a large, high-signal-intensity mass within the volar subcutaneous tissues. An indistinct plane with muscle anterolaterally (white arrows) suggests possible muscular involvement. Vasculature within the lesion produces small areas of signal void (black arrow).

plexiform masses, typically following the course of a peripheral nerve. A characteristic finding is the “target sign” of central low signal intensity and peripheral high signal intensity within tumor lobules (Fig. 60-21).⁵ A dominant mass within the lesion without this sign should raise concern about malignancy.⁵

Vascular Masses of Soft Tissue

Vascular lesions of the soft tissues^{17, 54, 61, 66} constitute a diagnostic challenge because of their substantial overlap in appearance. A single lesion may contain components of different histologic lesions.

Hemangioma

Hemangioma is the most common benign soft tissue mass of childhood. Lesions present at birth or shortly thereafter, grow disproportionately to the child in infancy, and involute in later childhood. Histologically, hemangiomas are composed of solid tissue.

MRI reveals a characteristic appearance (Fig. 60-22). The lesions are of strikingly high signal intensity on T2-weighted images and inversion recovery images. An enhancing soft tissue component is seen after gadolinium administration. Blood vessels within the lesion produce flow voids on spin-echo sequences and high signal on gradient-echo sequences because of fast flow. Involuting hemangiomas may have a “feathery” appearance from interspersed fat. Occasionally, enlarged blood vessels are seen supplying the lesion.

Lymphangioma

Lymphangiomas are composed of anomalous lymphatic channels and cystic spaces filled with fluid. On MRI, these lesions may produce an appearance similar to hemangiomas on T2-weighted images; unlike hemangiomas, however, they do not enhance homogeneously after gadolinium enhancement (Fig. 60-23). Cystic areas enhance only at

Figure 60-23. Lymphangioma of the thigh in a 7-year-old boy. A, Coronal inversion recovery image (TR = 4000 msec, TE = 25 msec, TI = 150 msec) shows a diffuse, multilobular, high-signal-intensity lesion principally within subcutaneous tissues. B, Postgadolinium axial T1-weighted image (TR = 650 msec, TE = 19 msec) with fat saturation shows minimal enhancement within interstices of the subcutaneous tissue. No soft tissue mass is defined. The fluid-containing cystic spaces do not enhance, but they do show peripheral enhancement (arrow).

Figure 60-24. Venous malformation of the leg in an 11-year-old boy. *A*, Axial T2-weighted image (TR = 4000 msec, TE = 85 msec) shows a high-signal-intensity multilobulated mass (arrow) deep within the musculature. *B*, Sagittal postgadolinium T1-weighted image (TR = 500 msec, TE = 16 msec) with fat saturation shows diffuse enhancement of the lesion. Note the vertically oriented venous channels within the lesion. *C*, Correlative fluoroscopic spot image of the lesion obtained after direct contrast injection into the lesion in preparation for sclerotherapy.

their periphery. No enlarged blood vessels are identified within or supplying the lesion.

Vascular Malformation

Venous malformations arise from abnormal development of veins. Phleboliths are commonly present on radiographs. On MRI, lesions are of intermediate signal intensity on T1-weighted images and of high signal intensity on T2-weighted images (Fig. 60-24). Flow

within venous malformation is stagnant; therefore, flow voids and bright gradient-echo signal are absent. MRI defines the extent of involvement of underlying muscle. Lesions enhance but without a soft tissue component.

Arteriovenous Malformation

Arteriovenous malformations represent a combined maldevelopment of arteries and veins with resultant shunting.

Figure 60-25. Myositis ossificans in a 9-year-old boy. *A*, Coronal T1-weighted image (TR = 600 msec, TE = 14 msec) with fat saturation shows an enhancing mass (arrows) within the proximal thigh. Enhancement is also seen within the adjacent soft tissues. *B*, The corresponding radiograph shows peripheral ossification within the lesion (arrows).

MRI shows a tangle of blood vessels with evidence of high flow and no soft tissue component.

Post-traumatic Soft Tissue Masses

Hematoma

Hematoma produces a high signal on T1-weighted images, suggestive of blood products. Ring enhancement is seen after gadolinium administration. In boys with hemophilia, hemophilic pseudotumors may develop as a result of repeated hemorrhage. Over time, these pseudotumors can cause remodeling of adjacent bone.

Myositis Ossificans

Myositis ossificans may produce an aggressive-appearing lesion on MRI, quite similar in appearance to malignant soft tissue lesions.⁴⁷ These masses are bright on T2-weighted images and inversion recovery and enhance markedly with contrast (Fig. 60-25). If the clinical history of preceding trauma is not obtained, the cause of the mass may not be suspected. Plain radiographs and occasionally, if necessary, CT demonstrate a characteristic peripheral distribution of ossification within the lesion, suggestive of the diagnosis. The CT appearance differentiates the lesion from a surface osteosarcoma.

Bone Marrow

Normal Appearance and Physiologic Conversion

To diagnose abnormalities of bone marrow in children, it is imperative to understand the normal appearance on

MRI and the changes that occur with age.^{13, 64, 73, 80, 88, 89} Hematopoietic marrow is of low signal intensity on T1-weighted images and is isointense to muscle on T2-weighted and inversion recovery images. Fatty marrow is of high signal intensity on both T1-weighted and T2-weighted images. With fat saturation or on inversion recovery images, fatty marrow is of low signal relative to hematopoietic marrow.

With gadolinium administration, there is a mild enhancement of hematopoietic marrow that lessens with age.^{3, 19} Fatty marrow does not enhance. Processes that replace normal marrow usually lower marrow signal on T1-weighted images, increase marrow signal on T2-weighted and inversion recovery images, and enhance with gadolinium.^{3, 62} Substantial marrow enhancement usually indicates a pathologic process. For MRI evaluation of marrow, images of the lower lumbar spine (sagittal plane) and pelvis and proximal femurs (axial and coronal planes) are obtained.

At birth, hematopoietic marrow is present throughout the skeleton (Fig. 60-26). The epiphyseal and apophyseal ossification centers convert to fatty marrow within a few months after ossification. Next, the diaphyses of the long bones convert, followed by the distal metaphyses and later the proximal metaphyses. In teenagers and adults, residual hematopoietic marrow persists within the axial skeleton. In older children, streaks of hematopoietic marrow create an inhomogeneous appearance of the metaphyses, particularly in the proximal humeri and femora (Fig. 60-27). Disease processes that stress the marrow, such as anemia, cause reconversion of marrow from fatty marrow to hematopoietic marrow. Reconversion occurs in the inverse order of the physiologic conversion caused by aging.

Figure 60-26. Normal bone marrow in a 9-week-old boy. Sagittal T1-weighted image (TR = 350 msec, TE = 16 msec) of the knee shows diffuse low signal intensity within metaphyseal and diaphyseal marrow, consistent with hematopoietic marrow. The proximal tibial ossification center is faintly visible (arrow). F, femur; T, tibia.

Bone Marrow Edema

Bone marrow edema is produced by traumatic injury, inflammatory processes, and tumors. Edema within the marrow space decreases the signal intensity of fatty marrow on T1-weighted images and produces high signal on T2-weighted images and inversion recovery. Margins are ill defined. Enhancement is seen beyond the confines of the underlying infection or tumor.

Hematopoietic Malignancy

Hematopoietic malignancies, namely leukemia and lymphoma, infiltrate and proliferate within the marrow space. Normal marrow is replaced by neoplastic cells. Diffuse decreased signal is seen on T1-weighted images. Increased signal is seen on T2-weighted and inversion recovery images. Enhancement with gadolinium may be subtle and is usually seen diffusely (Fig. 60-28).³ Marrow involvement with leukemia tends to be diffuse, but occasionally it is multifocal; however, marrow involvement with lymphoma tends to be multifocal but occasionally is diffuse. Metastatic disease may be multifocal or diffuse (see Fig. 60-7).⁹⁰

Effects of Therapy

Chemotherapy causes a depletion of hematopoietic marrow, causing fatty replacement. Marrow reconversion is seen during the recovery stage. Granulocyte colony-stimu-

Figure 60-27. Normal bone marrow in an 11-year-old boy. Coronal T1-weighted images (TR = 500 msec, TE = 10 msec) of the distal and proximal femurs. Slight inhomogeneous decreased signal within the metaphyses is caused by normal residual hematopoietic marrow, more prominent in the proximal metaphyses than distal metaphyses. The epiphyses and diaphyses of the femurs are completely converted to fatty marrow.

lating factor stimulates stem cell proliferation and hence reconversion (Fig. 60-29).^{26, 76} Described MRI findings after bone marrow transplant include hypointense peripheral bands in vertebral bodies, and diffuse homogeneous marrow hypointensity.^{7, 84} Both findings are thought to represent engrafting marrow. Radiation therapy causes bone marrow edema acutely, with subsequent marrow depletion with fatty replacement within the radiation field.^{85, 87}

Other Bone Marrow Disorders

In aplastic anemia, the marrow loses the ability to produce blood cells. There is diffuse and accelerated fatty replacement of hematopoietic marrow. In myelofibrosis, the marrow space is replaced by fibrotic tissue, yielding low signal on all MRI sequences. Disorders of hemoglobin synthesis and anemias, such as sickle cell disease, thalassemia, and spherocytosis, cause hyperplasia of hematopoietic marrow, which affects the entire skeleton. Hypertransfusion therapy may cause iron deposition within marrow. In these patients, marrow signal is strikingly low on all sequences (Fig. 60-30).⁵⁸

Bone Marrow Infarction

Bone marrow infarction is seen most commonly in children with disorders of hemoglobin production, such as

Figure 60-28. Acute lymphocytic leukemia in an 8-year-old girl. The patient initially presented with a 6-week history of knee pain and an elevated erythrocyte sedimentation rate and was thought clinically to have juvenile rheumatoid arthritis. *A*, Coronal T1-weighted image (TR = 700 msec, TE = 16 msec) shows diffuse low-signal-intensity abnormality within the metaphyses and diaphyses of the distal femurs and proximal tibias. A small area of normal marrow is seen in the left tibial diaphysis (*arrow*). Lesser abnormality can be seen within the epiphyses. *B*, Postgadolinium coronal T1-weighted image (TR = 650 msec, TE = 10 msec) shows increased diffuse enhancement of the abnormal marrow. The residual area of normal marrow (*arrow*) does not enhance.

Figure 60-29. Pelvis and proximal femurs of a 10-year-old girl receiving chemotherapy and granulocyte colony-stimulating factor. Coronal T1-weighted (TR = 300 msec, TE = 9 msec) image shows pelvic and femoral metaphyseal and diaphyseal bone marrow of low signal intensity, consistent with reconvalescence. The marrow of the proximal femoral epiphyses (*arrows*) is slightly decreased in signal because of early reconvalescence.

Figure 60-30. Thalassemia in a 3-year-old boy. A T1-weighted image (TR = 300 msec, TE = 16 msec) shows diffuse low signal intensity in vertebral and pelvic bone marrow caused by iron deposition. The low signal intensity within the liver (L) is also caused by iron deposition.

sickle cell disease, and in children taking steroids for various maladies. Bone marrow infarcts are of decreased signal intensity on T1-weighted images and of increased signal intensity on T2-weighted images. Enhancement may be seen on T1-weighted postgadolinium images. Differentiation between infarct and osteomyelitis may be difficult.⁶ Infarcts are typically metaphyseal or metadiaphyseal and have well-defined serpiginous margins. Osteomyelitis is less well defined.

Avascular Necrosis

General Considerations

Idiopathic avascular necrosis can affect a number of sites throughout the skeleton. Commonly affected sites include the capital femoral epiphysis (Legg-Calvé-Perthes disease), the capitellum (Panner's disease), and the tarsal navicular bone (Köhler's disease). Post-traumatic avascular necrosis is most common at the scaphoid, talar dome, and capital femoral epiphysis. When symmetrical or multifocal, an underlying disease process (e.g., sickle cell disease) or therapy (e.g., steroids) may be the cause.

Plain radiographs are often diagnostic of avascular necrosis; however, early in the disease process plain radiographs appear normal or minimally abnormal. Bone scintigraphy may show a "cold spot" in acute infarction. In the reparative stages, the scintigrams become less specific. On

Figure 60-31. Idiopathic avascular necrosis of the right femoral head in a 9-year-old boy. Postgadolinium coronal T1-weighted subtraction image (TR = 400 msec, TE = 14 msec) with fat saturation shows low signal intensity in the right femoral head (arrows), indicative of lack of normal enhancement. Some enhancement can be seen within the right femoral neck (curved arrow).

MRI, infarcted bone is of low signal intensity on T1-weighted images and high signal intensity on T2-weighted images.⁸¹ Devascularized portions of bone show a lack of enhancement after gadolinium administration (Fig. 60-31).

Legg-Calvé-Perthes Disease

Legg-Calvé-Perthes disease occurs most commonly in children from 4 to 8 years of age. Bilateral disease develops in 10% to 20% of patients; however, it is uncommon for both hips to show the same stage and degree of abnormality. If the abnormality is symmetrical, one should consider an underlying systemic disease process that may be predisposing the patient to avascular necrosis or to a skeletal dysplasia (e.g., Meyer's, epiphyseal, or spondyloepiphyseal dysplasia). MRI of avascular necrosis is most valuable early in the disease process when the diagnosis is in doubt.^{31, 51} Some investigators have used MRI during the treatment phase of disease.⁹³ Prognostic schemes have been proposed on the basis of the MRI findings.^{9, 18}

Infection and Inflammatory Processes

Osteomyelitis

Acute Osteomyelitis

Acute osteomyelitis in children is usually metaphyseal in location. Slow flow within sinusoidal end vessels at the metaphysis and decreased phagocytosis foster the deposition and growth of bacteria. In the axial skeleton, acute osteomyelitis has a propensity for sites equivalent to a metaphyseal area, such as adjacent to the triradiate cartilage or the vertebral end plates.

The initial imaging approach to suspected osteomyelitis is radiography. In a child with clinical signs and symptoms

of osteomyelitis and with radiographic findings consistent with the diagnosis, no further imaging may be necessary. More often, patients present with pain and fever early in the disease process, before bone destruction or periosteal new bone formation is evident on radiography. Traditionally, nuclear scintigraphy has been the next step in evaluation. Nuclear medicine is most valuable in patients when symptoms are poorly localized, when the site of disease is unknown, or when multifocal disease is suspected.

MRI for osteomyelitis is most productive when symptoms are localized so that a focused examination can be performed. MRI is indicated specifically when physeal or epiphyseal involvement is suspected, when the patient is thought to have spine or pelvic osteomyelitis, or when there is no response to therapy.⁴¹ In the latter instance, MRI can identify fluid collections or devascularized bone.

At MRI examination, acute osteomyelitis produces low signal intensity on T1-weighted images and high signal intensity on T2-weighted images and inversion recovery because of infiltration of the marrow space with inflammatory cells and edema (Fig. 60–32). Enhancement is seen

after gadolinium administration.¹² Margins of the lesion are ill defined, helping to distinguish infection from tumor, which may produce a sharp margin. Edema may extend into adjacent soft tissues. The presence of a subperiosteal fluid collection or abscess confirms the diagnosis of osteomyelitis and heralds the need for surgical drainage (Fig. 60–33).

Epiphyseal Osteomyelitis

Osteomyelitis may also be epiphyseal, resulting in a well-defined, rounded lesion. Either CT or MRI can be performed to characterize the lesion and to define its precise anatomic location.²

Subacute Osteomyelitis (Brodie's Abscess)

Subacute osteomyelitis represents a walled-off focus of less aggressive infection. Lesions are typically metaphyseal. A track leading to the adjacent physis is characteristic. The abnormality is well visualized on CT, particularly with the advent of longitudinal reconstructions (Fig. 60–34).

Figure 60–32. Acute osteomyelitis of the calcaneus in a 13-year-old. *A*, Axial T1-weighted image (TR = 600 msec, TE = 15 msec) shows low signal intensity in the posterior calcaneal body and adjacent apophysis (arrows). *B*, Sagittal inversion recovery image (TR = 4000 msec, TE = 29 msec, TI = 165 msec) shows increased signal in the same region (arrows). *C*, Coronal postgadolinium T1-weighted image (TR = 500 msec, TE = 17 msec) shows enhancement (arrows). Findings are not specific; however, no focal mass is identified to suggest a neoplasm.

Figure 60-33. Acute osteomyelitis of the distal radius (R) in an 8-year-old girl. Axial postgadolinium T1-weighted image (TR = 500 msec, TE = 14 msec) with fat saturation shows a subperiosteal abscess (arrows). Marrow of the radius enhances relative to the marrow of the ulna (U). Enhancement is also seen in adjacent soft tissues.

MRI demonstrates a layered appearance, which represents the layers of peripheral edema, sclerosis, and granulation tissue.

Chronic Osteomyelitis

Chronic osteomyelitis is the sequela of inadequately treated acute osteomyelitis. Chronic osteomyelitis is characterized by bony sclerosis, destruction, necrotic bone fragments (sequestra), cloaks of periosteal new bone containing the infection (involucra), and draining sinuses (cloaca). CT

Figure 60-34. Subacute osteomyelitis in a 6-year-old boy. Sagittal CT reformat image shows a well-defined lucent lesion (arrows) bridging the distal tibial growth plate.

can delineate the bony abnormality and can specifically identify small sequestra that are poorly visualized by MRI.^{33, 96} MRI can be performed to identify the extent of inflammatory tissue and to identify fluid collections to be drained.

Septic Arthritis

Most cases of septic arthritis of childhood are of hematogenous origin. Septic arthritis is most prevalent in the first decade of life. The hip and knee are most commonly affected. In the second decade of life, axial joints, particularly the sacroiliac joint, show greater involvement. For most joints, CT and MRI are not primary diagnostic modalities for joint infection⁴¹; nevertheless, for some children with joint infection, these techniques are used occasionally.

Infection produces a joint effusion. The synovium is inflamed and enhances briskly with contrast. Increased signal and enhancement may be seen in adjacent soft tissues. Some signal change and enhancement may be seen within the adjacent bone, even in the absence of infection. The MRI features of septic arthritis are nonspecific; other inflammatory joint conditions may have a similar appearance.

Juvenile Rheumatoid Arthritis, Hemophilia, and Pigmented Villonodular Synovitis

Juvenile rheumatoid arthritis (JRA), hemophilia, and pigmented villonodular synovitis (PVNS) have overlapping MRI imaging characteristics. All three processes are characterized by the presence of effusion and synovitis.^{32, 42, 67}

Patients with JRA may show extensive pannus formation. This is seen as enhancing periarticular soft tissue, often with associated bone erosion.³⁷ Erosive changes can also be seen because of the synovial proliferation seen in PVNS. PVNS and hemophilia are both characterized by iron deposition within the synovium resulting from repeated hemarthrosis (Fig. 60-35).^{42, 67} Occasionally, PVNS presents in a more localized form as a focal soft tissue mass.

Dermatomyositis

Dermatomyositis is an autoimmune condition not infrequently presenting in childhood. The disease process is characterized by muscle weakness and elevated blood levels of muscle enzymes and inflammatory markers. Skin disease may be minimal. Proximal muscles, particularly in the pelvis and proximal lower extremities, are affected in symmetrical fashion.

MRI can be used to confirm the diagnosis, delineate the extent of involvement, guide biopsy, and assess response to therapy.³⁴ In the acute stage of the disease, involved muscles have increased signal intensity on T2-weighted images and inversion recovery (Fig. 60-36). Strands of fluid are seen within septations between muscle bundles. The abnormality is occult on T1-weighted images. Gadolin-

Figure 60-35. Persistent knee joint effusion in a 12-year-old boy with hemophilia. *A*, Axial proton-density image (TR = 4000 msec, TE = 15 msec) with fat saturation shows a large effusion (E) with marked synovial proliferative changes. *B*, Sagittal gradient-echo image (TR = 31 msec, TE = 15 msec, flip angle = 30 degrees) shows low-signal-intensity artifact from chronic hemosiderin deposition (arrows). F, femur; Fi, fibula; P, patella; T, tibia.

ium is not required. In advanced disease, fatty infiltration of the involved muscle may be seen.

Pyomyositis

A focus of infection within muscle is defined as pyomyositis. Pyomyositis can be solitary or multifocal. If multifocal, an underlying source, such as endocarditis, should be sought. Early in the disease process, an ill-defined increased signal within the involved muscle can be visualized. This progresses to the formation of an abscess within the muscle (Fig. 60-37). At this stage, MRI can identify a focal fluid collection with an enhancing rim within the muscle. The abnormality usually appears larger on T2-

weighted fat saturation and inversion recovery images than on gadolinium-enhanced images because of the adjacent edema.

Necrotizing Fasciitis

Necrotizing fasciitis is an infection of the fascial planes of soft tissue. The infection can spread rapidly, subjecting the patient to substantial tissue loss and even death. MRI can be performed to help confirm the diagnosis and to define the extent of abnormality as a guide to therapy. MR images show edematous changes infiltrating deep fascial planes with fluid collections and enhancement after contrast

Figure 60-36. Dermatomyositis in a 13-year-old girl. Axial T2-weighted image (TR = 2500 msec, TE = 80 msec) with fat saturation shows symmetrical increased signal intensity within anterior thigh musculature. The relative sparing of the hamstring muscles posteriorly (arrows) is characteristic.

Figure 60-37. Pyomyositis in an 11-year-old girl. Axial postgadolinium T1-weighted image (TR = 417 msec, TE = 12 msec) with fat saturation shows intramuscular abscesses (arrows) within both legs. Multiple additional abscesses were present within both legs. No source was identified. A drain was placed in the right calf abscess under sonographic guidance.

administration.⁷⁹ In contradistinction, in cellulitis the inflammatory changes involve subcutaneous tissues and superficial fascia. An aggressive cellulitis may simulate necrotizing fasciitis on MRI.⁷⁹

Trauma

Fracture

Radiographs delineate most fractures adequately such that further imaging is not usually necessary. CT is commonly used to delineate fractures of the axial skeleton that are incompletely shown by radiographs. Within the appendicular skeleton, CT is less often needed. In the pediatric population, CT is used to assess juvenile Tillaux and triplane fractures of the distal tibia, with specific reference to distraction or offset of fragments at the articular surface (Fig. 60–38).²³ CT is occasionally used to assess the adequacy of reduction of growth plate fractures in younger children, particularly Salter IV fractures, in which the incidence of premature fusion is increased by malalignment of the fracture fragments at the growth plate.

MRI identifies a fracture as a linear abnormality of low signal intensity on T1-weighted images and high signal intensity on T2-weighted images. It is also adept at demonstrating fractures of the growth plate, which may be occult to other imaging modalities.⁴⁰ In the infant who lacks ossification, MRI can define fractures that pass through the cartilaginous model of a growth center or through the adjacent growth plate. In older children, fractures involving the growth plate can occasionally be subtle on plain radiography. MRI demonstrates increased signal intensity within the fractured portion of the growth plate, accompanying metaphyseal or epiphyseal fracture lines, bone marrow edema, periosteal elevation or disruption, associated soft tissue edema, and joint effusion (Fig. 60–39).

Acute scaphoid fractures can be occult on radiographs. When there is a strong clinical suspicion but initial radiographs are negative or equivocal, the patient can be immobilized and follow-up films obtained. Alternatively, either CT or MRI can be performed.¹¹ MRI should be performed

Figure 60–38. A juvenile Tillaux fracture of the distal tibia in a 14-year-old boy. Coronal CT reformat image delineates the transverse fracture line through the lateral growth plate (arrowheads) and the sagittal fracture line through the epiphysis (arrow). The width and alignment of the fracture at the articular surface can be well visualized.

Figure 60–39. Salter II fracture of the distal femur in a 12-year-old girl. Coronal T2-weighted image (TR = 4200 msec, TE = 120 msec) delineates the fracture as a high-signal line in the metaphysis (arrows) and increased signal within the lateral growth plate (arrowheads). b, bone marrow edema. Periosteal elevation is indicated by curved arrows.

in a dedicated wrist coil. CT images are obtained with narrow collimation to allow reconstruction in other planes. Positioning the long axis of the scaphoid parallel to the CT scanner gantry (radial deviation) improves resolution of a fracture. In follow-up, CT is helpful to assess the nonunion of a scaphoid fracture and bony collapse. Both CT and MRI can be used to assess for proximal pole avascular necrosis caused by disruption of its recurrent blood supply. Acutely, no abnormality is seen on CT. More advanced avascular necrosis produces a sclerotic appearance of the proximal pole. On MRI, the avascular segment demonstrates low signal intensity on T1-weighted images because of edema acutely or sclerosis later.¹¹ On a T2-weighted scan, the avascular segment has high signal intensity. If gadolinium is administered, the avascular segment fails to enhance.

Stress Fracture

Children tend to experience stress fractures at a variety of locations throughout the body. The lower extremities are affected most frequently. The clinical history and physical examination are usually suggestive. Plain films may suffice for diagnosis. Bone scintigraphy, CT, or MRI may be performed when the diagnosis is unclear.^{56, 99}

CT shows evidence of nonaggressive periosteal new bone formation.⁹⁹ On MRI, the affected bone shows decreased signal intensity on T1-weighted images and increased signal on T2-weighted and inversion recovery im-

Figure 60-40. A stress fracture of the distal femur in a 14-year-old boy. The patient had a remote history of Wilms' tumor but was also a cross-country runner who had recently increased his training. Coronal T2-weighted image (TR = 4800 msec, TE = 60 msec) shows increased signal within the distal femoral metaphysis and adjacent soft tissues. A transverse band of decreased signal corresponds to a band sclerosis (arrows) seen on subsequent radiographs.

ages.⁵⁶ Both CT and MRI may show cortical thickening. Edema is seen within adjacent soft tissues; however, no associated soft tissue mass is identified. In advanced cases of stress fracture, a distinct fracture line may be identified (Fig. 60-40). The MRI findings of stress fracture may be nonspecific and difficult to separate from infection or tumor. Correlation with plain radiographs is imperative.

Osteochondritis Dissecans

Osteochondritis dissecans is probably a sequela of trauma. Although the femoral condyles are the most common location, osteochondral injury is also seen at the talus, patella, and capitellum.^{14, 16, 68} At the knee, the classic location is the lateral aspect of the medial femoral condyle. Patients present with joint pain and swelling.

The prognosis and treatment of osteochondral injuries depend on the size of the lesion and its stability. It is important to determine whether there is a bone fragment within the defect, whether the bone fragment is affixed to the underlying bone, and whether the overlying cartilage is intact.¹⁵ CT is occasionally performed to characterize the defect and identify the bone fragments. Without intra-articular contrast, CT cannot define cartilage integrity. CT arthrography can be used to identify loose bodies within the joint, with precontrast images to assess for osseous fragments and postcontrast images to assess for cartilaginous fragments.

MRI is excellent for assessing osteochondral injury (Fig. 60-41).^{14-16, 69} The size of the defect and the presence of a fragment within the defect are readily confirmed. High signal intensity at the interface between the fragment and the underlying bone suggests that the fragment is unsta-

Figure 60-41. Osteochondritis dissecans in a 14-year-old girl. The 3D-gradient-echo image (TR = 60 msec, TE = 7 msec, flip angle = 40 degrees) with fat saturation shows a nondisplaced fragment within a defect within the medial femoral condyle (arrow). The overlying cartilage appears to be intact.

ble.¹⁵ Cartilage sequences can usually define the integrity of the overlying cartilage. Intra-articular gadolinium can also be used to assess cartilaginous integrity as well as to define the stability of a fragment. Gadolinium seen between the fragment and the underlying bone suggests an unstable fragment. MRI does have some limitations in assessing for intra-articular loose bodies. The presence of a joint effusion makes identification of loose bodies easier.

Soft Tissue Injury

As in adults, MRI in children is adept at identifying and defining injuries of muscle, tendons, and ligaments.^{45, 101} Ligamentous injury is relatively uncommon in the young

Figure 60-42. Bilateral discoid lateral menisci in a 9-year-old boy who complained of "clicking" within both knees. Coronal proton-density image (TR = 4500 msec, TE = 21 msec) shows abnormally large lateral menisci (arrows). Increased signal within the substance of the menisci may represent early degeneration, although no tear is identified.

Figure 60-43. Post-traumatic growth arrest of the proximal tibia in an 11-year-old boy. A coronal CT reformat image from 1-mm collimation helical source images shows a focal bony bar (arrow) joining metaphysis (M) to epiphysis (E) across the growth plate. A growth line (arrowheads) is tethered by the bony bar. This bar was resected.

child because the growth plates are not yet fused and thus represent a site of relative weakness. Some degree of inherent ligamentous laxity in children also contributes to the lower incidence of ligamentous injury. Lateral compartment contusions, usually indicative of an anterior cruciate ligament (ACL) tear in adults, may be seen in children with an intact ACL.⁸³ Once the growth plates have fused, the adolescent is prone to many of the same ligament and tendon injuries seen in young adults. These injuries are detailed in Chapter 48, The Knee.

A few particular sites of injury warrant specific comment. The ACL is rarely injured prior to fusion of the physes; however, the presence of open physes and the diagnosis of physeal fracture do not necessarily exclude the presence of ACL injury. Avulsions of the tibial spines, and hence the ACL, are not infrequent in children. Discoid menisci should be suspected in younger children with meniscal injuries, particularly if the lateral meniscus is involved (Fig. 60-42).⁸²

Foreign Body

Although sonography is preferred at superficial locations, both CT and MRI have been employed to confirm the presence of soft tissue foreign bodies and to delineate their location.

Growth Plate Arrest

The most common cause of premature growth plate fusion is trauma. Other causes include infection, thermal injury, and frostbite. Radiographs are often sufficient to make the diagnosis. Both CT and MRI have been employed to confirm premature growth plate fusion and to delineate its extent for planning operative therapy.

Growth plate fusion is assessed by CT with narrow collimation axial source images and reconstructions in the coronal and sagittal planes. Areas of premature fusion are

Figure 60-44. Post-traumatic growth arrest of the distal femur in an 11-year-old boy. A, Coronal gradient-echo image (TR = 500 msec, TE = 12 msec, flip angle = 60 degrees) with fat saturation shows an extensive area of fusion (arrows) within the lateral aspect of the distal femoral growth plate. A small cartilaginous inclusion in the metaphysis is indicated by the curved arrow. B, Axial maximum intensity projection image obtained from 3D-gradient-echo images maps the area of growth plate fusion (arrows). Because the area of fusion was extensive, resection was not attempted. The patient subsequently underwent an Ilizarov limb-lengthening procedure. P, patella.

seen as sclerotic bridges of bone crossing the growth plate (Fig. 60-43).⁹⁸ Larger areas of fusion may lead to medullary continuity between metaphysis and epiphysis. Growth lines may be seen within the adjacent metaphysis, tethered to the physis by the site of fusion. Premature physal fusion can also be assessed by MRI with cartilage-sensitive gradient-echo images or proton-density images with fat saturation.⁸ Areas of premature fusion are seen as low-signal-intensity defects within the high-signal-intensity physis. Maximum intensity projection images in the axial plane map the extent of fusion (Fig. 60-44).⁸

Developmental Abnormalities

Congenital Limb Anomalies

In children with congenital limb-reduction anomalies, MRI may be used to delineate the cartilaginous model of

bone before ossification.⁵⁵ MRI is particularly valuable in cases of proximal focal femoral deficiency in determining whether there is continuity of the femur (Fig. 60-45).

Developmental Dysplasia of the Hip

CT can be used to determine the relationship of the femoral head to the acetabulum during treatment of developmental dysplasia of the hip.^{20, 32} CT is particularly valuable after operative reduction, when an overlying cast diminishes the value of plain radiographs (Fig. 60-46).

Targeted axial images are centered at the level of the hips. A reduced milliampere-second (mAs) setting can be employed. If concentrically positioned, the femoral head is located immediately over the triradiate cartilage. Prior to ossification, the position of the femoral head is less well delineated; however, its position may be inferred from the position of the proximal femoral metaphysis. In cases of

Figure 60-45. Proximal focal femoral deficiency in a 19-month-old boy. **A**, Radiograph shows no ossified right femoral head. The proximal femur is diminutive and displaced superolaterally. A relatively well formed right acetabulum (*arrowheads*) suggests the presence of a right femoral head. The left hip and femur appear normal. **B** and **C**, Coronal gradient-echo images (TR = 60 msec, TE = 7 msec, flip angle = 40 degrees) show displacement of the proximal right femur (*short arrows*) with a cartilaginous greater trochanter growth center at its cephalad aspect (*curved arrow*). A separate femoral head (*long arrows*) with a small early ossification center is seen within a relatively well formed right acetabulum (*arrowheads*). g, greater trochanter; L, left proximal femoral epiphysis.

Figure 60-46. Bilateral developmental dysplasia of the hips in a 2-month-old infant wearing a spica cast. Apart from the scout topogram, these two axial images constituted the entire CT examination. The images were obtained with 40 milliamperes-seconds (mAs). Neither femoral head is ossified. *Top*, Right hip reduced, with the femoral metaphysis (R) in correct alignment with the right acetabulum. *Bottom*, persistent posterior dislocation of the left hip (L).

failed reduction, CT may identify tissue (pulvinar) or ilio-psoas tendon interposed between the femoral head and the acetabulum.³⁵

Femoral Anteversion/Tibial Torsion

Rotational anomalies of the femur or tibia may produce in-toeing, genu valgum, and gait abnormalities. Femoral anteversion refers to the anteriorly directed angle the femoral neck makes relative to the femoral shaft. Tibial torsion refers to the rotation of the proximal tibia relative to the distal tibia. Although rough assessments of femoral anteversion and tibial torsion can be obtained through physical examination, CT provides a more precise delineation.³⁶

To measure femoral anteversion, limited axial images are obtained through the femoral neck and femoral condyles (Fig. 60-47). The difference in angulation between the axis of the femoral neck and the femoral condyles determines femoral anteversion. The normal measurement

decreases with age, from an average of 32 degrees at birth to 16 degrees at 16 years of age.^{36, 75} Tibial torsion is measured by a similar method.⁵⁰

Tarsal Coalition

Calcaneonavicular and talocalcaneal are the most common forms of tarsal coalition. Patients most commonly present in the second decade of life with foot pain and flatfoot deformity. Early in childhood, coalitions are not evident on CT or plain radiographs, since they are cartilaginous or fibrous. With maturation, the coalitions increase in symptoms and radiologic conspicuity.

Calcaneonavicular coalitions form between the anterior process of the calcaneus and the posterolateral aspect of the navicular bone. Calcaneonavicular coalitions are well seen on oblique radiographs of the foot. CT is not usually required. Talocalcaneal coalitions form at the middle facet joint and involve the sustentaculum tali of the calcaneus. Talocalcaneal coalitions may be suspected on the basis of plain radiographs; however, they are better seen with CT.⁹⁵ Coronal images demonstrate osseous continuity of the talus and calcaneus or, in the case of fibrous union, close apposition of the bones with lack of the normal joint space and deformity, suggesting union (Fig. 60-48). Images can be obtained directly in the coronal plane or reconstructed from an axial acquisition. MRI has also been used to assess for tarsal coalition and is particularly helpful in nonosseous coalition.⁹⁵

Figure 60-47. Recurrent right hip dislocation in a 9-year-old girl with cerebral palsy. Axial CT images obtained at the levels of the femoral necks (*top*) and the femoral condyles (*bottom*) are used to measure anteversion. The difference in angulation between the axis of the femoral neck (line A) and the transcondylar axis (line D) gives the angle of anteversion. The transcondylar axis is determined by bisecting the angle formed by tangent lines along the anterior (line B) and posterior (line C) aspects of the femoral condyles. The subluxated right femur is anteverted compared to the left femur.

Figure 60-48. Tarsal coalition in a 15-year-old boy. The direct coronal CT image shows osseous continuity of the left talus and calcaneus at the middle talocalcaneal joint (arrow). The right side is normal.

Image-Guided Micro Procedures: CT and MRI Interventional Procedures

John R. Haaga

Image-Guided Microsurgery—New Name, Topics, and Innovations

Since I performed the first CT-guided procedure in 1975 (Fig. 61-1), this field has progressed remarkably. Nonvascular interventions have finally gained their appropriate role in medical practice today and stand on an equal par with vascular interventions. The use of CT and MRI procedures has become ubiquitous in every hospital in the country, if not the world. Even tiny hospitals with census of five or six patients have occasional CT-guided procedures and in fact demand that such services be provided. The scope and sophistication of these procedures continue to increase.

It is my very strong opinion that radiologists will maintain control over the field of imaging only if they continue to master and develop these image-guided procedures. Multislice scanners and sophisticated MRI devices display anatomy and pathology so well that other clinical groups can learn the major facets of our field. The procedures set us apart from the other physician groups and represent a unique skill set that is not easily mastered by casual observation. It is critical that we continue development and refinement of these valuable methods. Those who develop, use, and refine these interventional techniques will control the field of imaging. Furthermore, it is imperative that we begin to better describe our field so it develops a distinct identity among the public and other physicians. Assigning a new name to these valuable procedures will go a long way in establishing this identity.

The old term of *interventional radiology* does not communicate the essential elements of our methods. We basically use imaging to guide our procedures, and we use instruments smaller than those of the minimally invasive techniques of the surgeons. For both ease of communication and better identification of our art, I believe we should call these techniques *image-guided microsurgery*.

New Topics and Information

When textbooks have had numerous editions, the authors run the risk of repeating major portions of earlier work and readers run the risk of purchasing a book that is

partially outdated and presents little new information. For these reasons I feel compelled to mention in the beginning of the chapter the major changes that have occurred.

The historical sections have changed to reflect the remarkable refinements in the field of image-guided microsurgery. Knowledge of the historical evolution of these methods minimizes the possibility that authors might retrace old pathways. The old adage about human history is of course applicable to interventional procedures: "Those who do not know history are condemned to repeat it."

The main body of this chapter has been totally rewritten. Older material has been deleted and new information provided. The highlights of the chapter are the new approaches to needle techniques and the discussion of new assistance methods for interventional approaches. New methods of anatomic approach are included in the areas such as the middle mediastinum, hemostasis in coagulopathic patients, and use of chemical agents and drugs to improve the treatment of infections and tumors.

Diagnostic Imaging Versus Procedures

Some radiologists have looked at procedures as time consuming and not an important part of their practice. Nothing could be farther from the truth. Diagnostic imaging studies are important, but interventional procedures are even more critical for patient care, the preservation of radiology, and advances in medicine at large. Despite the most remarkable development and evolution of imaging modalities, definitive diagnosis and treatment of patients are still dependent on examination of tissue samples. Such tissue samples are even more critical now because current and future therapy is dependent on definitive characterization of the many tissue factors such as specific cell type, enzyme content, DNA profile, proteomic character, and other physiologic parameters. Surgical methods for obtaining such samples have been largely supplanted by image-guided procedures that are more accurate and cost-effective and have much lower morbidity and mortality.

Of even more importance than the diagnostic biopsies is the development of therapeutic techniques for the treatment of infections and tumors. Current treatment modalities

Figure 61-1. A, First CT guided biopsy was of a retroperitoneal mass (by the author). Even though the results of this biopsy were negative, the merits of CT guidance were obvious. B, First CT-guided procedure of the lung in 1975 (by the author).

include catheter drainages for abscesses, lymphoceles, hydronephrosis, gallbladders, and even loops of bowel. The treatment of tumors is a major part of percutaneous procedures by local chemical injection, local radiofrequency treatment of tumors, and, in the near future, direct deposition of chemotherapeutics, DNA transfer agents, RNA agents, peptides, or other compounds.

This chapter is somewhat longer than others because of my intense interest and extensive experience. I performed the first CT biopsy and drainage procedures in 1975 and 1976 and have continued to perform such cases on a daily basis (see Fig. 61-1). We also developed the "longitudinal scan" in 1976 (Fig. 61-2), which was the precursor to all of the current localization scans. The basic principle of performing axial procedures is demonstrated in Figure 61-3A. It is fascinating to note the progress to date, wherein we are beginning to use robots to assist in such procedures (Fig. 61-3B, C). The usefulness of MRI scans for revealing subtle pathology was evident in the beginning, but the advantage of clear instrument visualization by CT has always been apparent (Fig. 61-4).

Guided MRI procedures have become an integral part

of the interventional methods, and I am proud to say, have been refined and perfected by several of my colleagues.²⁴⁰ MRI procedures have yet to play a major role in the daily routine of most departments, but major refinements and developments in the field of MRI interventions continue.

Although many different techniques and methods have been reported and are unquestionably effective, I am confident that our techniques developed over many years and after literally thousands of procedures are valuable and compare favorably to other proposed methods.

History of Percutaneous Procedures

Reviewing the historical perspective of interventional CT procedures can be somewhat confusing if one takes a narrow viewpoint and assumes that their evolution in the past 50 years has been along a single pathway. If one takes an objective, global viewpoint, however, one can see that the development of percutaneous procedures has been quite varied and has involved four separate disciplines: instrument development, clinical techniques, pathologic and cytopathologic techniques, and guidance methods.

Figure 61-2. A, First, CT radiographic image ever produced or reported. One of its original purposes was to aid with interventional procedures (see later portion of chapter on catheter insertions). This primitive scan shows the lower chest and upper abdomen. This preceded all of the current commercial images including the Topogram, Scoutview, Synerview, etc. The originator (J.R. Haaga) reported and published this figure, but he was not clever enough to obtain patents at the time! B, Modern image showing the remarkable detail of current images. The image of this patient shows the abdominal anatomy and several catheters, wires, and monitoring devices. (A, From Haagal JR. et al: CT longitudinal scan. AJR 127:1059-1060, 1976.)

Figure 61-3. A, Placement of a biopsy needle within an anatomic location. The relationship of the needle to both the plane of the z axis and the plane of the x-y axis is illustrated. B, C, Current approaches have evolved far beyond earlier methods and even initiated developmental work with robotic assistance. B, CT scanner with robot mounted on the side of the table, placing the instrument in a swine model. C, CT scan taken after insertion of the needle by the robot, to a site adjacent to aorta. This corresponds to the celiac plexus. With the positive results of these tests, I am convinced robotics will be used in future devices. See section on assisted guidance. A

B

C

The advances in these four areas have at times occurred concurrently, and it is difficult to appreciate the overall perspective if one selectively reads the literature. Furthermore, as one reads the various reports in the literature, one must be aware of individual bias relative to data interpretation and reference sources. When authors look to the literature to support the thesis of their report, they have a natural tendency to use only the information that supports their viewpoint. For this reason it is most important that in some cases the informed reader consult the primary reference source rather than relying strictly on the author's interpretation (this applies even to the reading of this chapter).

The best way to demonstrate this complex premise is to

explore the example of the small-caliber, or "skinny," needle. In many reports authors refer to the experience of Lundquist to support the accuracy of the ultrasonic-guided skinny-needle biopsy, despite the fact that Lundquist performed only "blind" biopsies with the skinny needle.^{255,256} In addition, Lundquist is frequently quoted in attempts to prove the safety of the skinny needle compared to the large cutting or Menghini-type needle. If readers take a more comprehensive approach to the literature, however, they will find that in his final dissertation, Lundquist noted a favorable result with large needles as well as with the skinny needle. Using the skinny needle first to probe the pathway for the large needle, Lundquist had performed more than 1000 procedures with the Menghini needle with

Figure 61-4. These scans show an MR-guided procedure and a CT-guided procedure of a liver lesion. A, This MR scan shows the low-intensity mass within the left lobe much more clearly than does the CT scan. The needle (arrow) is difficult to see. B, This CT scan taken at the same level shows the visualization of the needle in the same mass. With current technology, the best result in such cases is to correlate the location on the MRI scan with the CT during biopsy.

“no complications” (of 2611 cases involving the use of the skinny needle, he reported one hematoma). His data are valid within the complete context of his work and the literature, but one may draw incorrect conclusions if only selected sources of information are used.

Progress from 1930 to 1960

From 1930 to 1960 most progress in percutaneous biopsies was made in the area of unguided clinical methods and instrument development. There was very little progress in the development of pathologic techniques or guidance by imaging.

Two important clinical points concerning liver biopsy were discovered during this period. First, for blind procedures, the intercostal approach was found safer than the anterior subcostal approach (if the liver was not massively enlarged). Second, the liver biopsy was proved safer when performed while the patient suspended respiration and motion. The importance of this latter clinical procedure was emphasized by Menghini,²⁷² who introduced his “1-second” technique. Menghini’s real contribution was his recommended method of having the patient suspend respiration while the biopsy is quickly performed. Motion by the patient was thus avoided and possible injury to the liver was minimized. This “breath-holding” maneuver, and not the needle that bears his name, was his significant innovation.

Instrument development during this time was confined to the various types of cutting needles. Instruments introduced included the end-cutting needles, the Vim-Silverman needle, and the Tru-Cut needle. A number of general review articles were published about the incidence and cause of the complications associated with blind, large-needle liver biopsy. These complications included hemorrhage, bile peritonitis, and gallbladder perforation. The major causes of hemorrhage were abnormal prothrombin time, severe liver disease, and abnormal vessels. Although it now

seems astonishing, biopsies were performed on patients who had very abnormal prothrombin times. The major cause of bile peritonitis was caused by penetration of dilated bile ducts with obstructive jaundice or perforation of the gallbladder (most frequent with an anterior subcostal approach).

These review articles about the complications of large-needle biopsy are especially interesting to note because these very old articles are typically quoted in the radiology literature to discourage the use of the larger cutting needles. Obviously, comparisons of today’s guided techniques with the results of the old articles are completely invalid. Current methods of patient selection, detection of coagulopathy, local anesthesia, and patient sedation are remarkably different from those of the early authors. Furthermore, modern CT techniques eliminate almost all potential causes of complications with the large needles.

Biopsies of the liver and/or lung were performed either blind or with the assistance of “red goggle” fluoroscopy. Blind localization for these procedures required either palpation, percussion, or approximated localization from plain radiographs. Fluoroscopic guidance using direct visualization or a phosphored glass screen (no image intensification on television) required that the radiologist localize the abnormality for the clinician. After localization by direct fluoroscopy in a darkened room, the biopsy procedure was performed by a clinical physician with the lights on. The radiologists donned their red goggles so that their eyes could remain accommodated for the dark, direct fluoroscopy (black images on green phosphor). Biopsies were not a radiologic procedure during this era.

Progress from 1960 to 1970

Development during the 1960s included comparison data about the various large cutting needles, introduction of cytopathologic methods, introduction of the skinny nee-

dle for blind biopsies, and the first "break-through" with guided biopsies: image intensification fluoroscopy.

Qualities of the different cutting needles were compared by Parker et al.³²¹ Their comparison of the Vim-Silverman needle with the Menghini needle showed that the latter was superior for sample recovery. The adequacy of sample was 94% for the Menghini needle compared with 77% for the Vim-Silverman needle. They also noted the higher incidence of complications with the Vim-Silverman needle. The advantages of the Menghini method using the end-hole needle were its simplicity, the short time required for the procedure, and lack of patient respiratory motion.

During this period the development of cytopathologic techniques revolutionized percutaneous procedures. Although earlier authors such as Martin²⁶⁴ used a cytologic method, Soderstrom²⁰⁴ in 1958 and 1966 developed and reported the first well-defined method of needle aspiration and cytopathologic evaluation. Several of his protégés, including Lundquist^{255,256} and Nordenstrom,³⁰⁴ continued this work and reported extensively on the clinical application of these techniques (discussed later).

Aside from these workers, other authors evaluated the usefulness of the cytopathologic techniques on material obtained from cutting needles rather than on the aspirates from the skinny needle. Grossman et al,¹²⁹ using tissue and fluid from Menghini biopsy of the liver, performed cytopathologic studies of the fluid and "touch preps" of the tissue on slides. They found that their diagnostic accuracy for malignancy improved by an additional 15%, compared with the histologic results of the tissue core. Later work by Atterbury et al⁷¹ confirmed their observations, but these results were not quite as remarkable. From their study they found that in their series of 29 malignancies, the yield improved only by 3% (one patient).

These articles, which were very frequently misquoted during the 1980s, show the added benefit of the cytologic techniques on the samples obtained with larger cutting needles (in addition to the traditional histologic methods) for the detection of malignant cells. These articles were not comparisons between the skinny needles and the large needles (discussed later).

After the positive results reported by these authors and the experience of Soderstrom,³⁶¹ other authors began clinical trials using a small-caliber, or skinny, needle for unguided procedures to obtain liver samples for cytologic examination. One of the largest series about skinny-needle biopsy of the liver was Lundquist's study in 1970 about unguided or blind biopsies of the liver. In his first report²⁵⁵ about a series of 1748 liver biopsies, he correctly made the diagnosis of cancer in 74% of patients (50 of 74) with no complications. No mention is made concerning the diagnosis of benign disease in the remaining 1674 cases. In this series of malignant cases the authors were able to make the prospective specific diagnosis in only 2 metastatic lesions and 5 of 10 hepatomas. Lundquist's intent was to develop a safe screening method for detection of tumor that would permit a wide latitude of technique error without significantly endangering the patient.²⁵⁵ He did not refute the advantage of the larger needles to make a more definitive diagnosis. In Lundquist's later report of a larger series,²⁵⁶ he reported an equivalent diagnostic accuracy with one serious complication of bleeding. In this paper he also

related his experience of 1000 large-needle biopsies with no complications. The important point of avoiding complications, he believed, was the evaluation of the chosen entrance site by probing with a skinny needle before using the large needle. In this fashion he could avoid bowel, lung, gallbladder, vessels, or excessively vascular tumors (current CT methods provide the same information and advantage).

One of the few comparison studies of different needles during this time was by Johansen et al,¹⁹⁵ who compared the use of a skinny needle with a Menghini needle in blind liver biopsy. These authors found identical results for the detection of malignancy; both needles were correct for 6 of 12 cases. There were no complications.

With this initial experience and the development of image intensification television as a background, radiologists began to evaluate the merits of the skinny needle for sampling the lung with fluoroscopic guidance. In 1966 Dahlgren and Nordenstrom⁶⁶ began using image-intensified fluoroscopy to guide the skinny needle for biopsy of lung masses. Their result showed a high accuracy and a low complication rate.

These early workers clearly established the usefulness of the skinny needle for obtaining samples from epithelial tumors such as adenocarcinoma and squamous cell carcinomas. Such tumors lack the cellular organization or "cement" to bind them together. Therefore, the nontraumatic skinny needle can recover such loosely adherent cells. They also noted that when other than epithelial tumors were biopsied by these methods, the results were good but diagnoses were not as specific. This was especially true when architecture was important, such as in cases of lymphoma, benign tumors, or neurogenic tumors.

Television image intensification has made a remarkable contribution to the performance of biopsy procedures. With red goggle fluoroscopy, radiologists could not turn room light on and off during a procedure because of eye accommodation. With the direct fluoroscopy, radiologists had to enhance their visualization of the dark fluoroscopy by preceding their examinations with a period of wearing the red goggles to accommodate their eyes. With image intensification, which improved light output by a factor of 1000, radiologists could turn lights on and off and thereby assume direct responsibility for the procedures.

Progress from 1970 to the 1980s

During the period of the 1970s and 1980s, more progress was made with percutaneous procedures than during any of the previous periods. Progress was rapid because of the excellent groundwork by earlier workers and because of the remarkable technologic advances. Some refinement was made in the cytopathologic area, but remarkable progress was made in the areas of clinical experience, instrument evaluation, and imaging guidance.

Before outlining the progress made with the skinny needle and the various imaging systems, some comments about clinical work with the cutting needles are appropriate. First, a prospective series in 1978 by Perrault et al³²⁷ showed no complication difference among the Vim-Silverman, Menghini, and Tru-Cut needles. This is fascinat-

ing, considering the significant difference in both the calibers and cutting actions. One might conclude that, if there are any basic differences in complications due to needle configuration, good clinical technique and experience can compensate, so that complication rates are equivalent. To further support this point, Bateson's comparison²¹ in 1980 of the Tru-Cut needle and the Menghini needle showed no diagnostic or other complications, although the physical integrity of the sample was more consistently intact with the Tru-Cut needle, especially with cirrhotic livers.

The two other significant events that occurred in the 1970s were the introductions of ultrasound²² and CT as guidance modalities. Ultrasound was introduced as a biopsy guidance system by Holmes et al^{178,179} in 1975. CT guidance was introduced by Haaga et al¹³⁸ in 1976.⁷⁷ As noted later, both of these later imaging systems have developed into valuable tools for sampling different areas.

The 1980s

In the early 1980s, the cutting needles, both side-cutting and end-cutting, came into their prime.^{137,146,150} With the advent of the automated needles, many radiologists now use these devices almost routinely. Other major advances undoubtedly would be made during the 1990s, the seminal work appearing in the literature clearly indicating the directions.

With further development of biopsy devices, I am confident that a hemostatic biopsy device will be developed and introduced. The first indication of the potential of such a device was reported by Gazelle et al.⁴⁹ In this initial work by our group, a hemostatic sheath, which could be deposited at the site of the biopsy procedure, was developed. In animal models using anticoagulated pigs, it was shown that such a device could prevent significant bleeding in the liver. It is probable that a recent modification of this device could reach the market in the next several years and potentially result in a "risk-free" biopsy.

More sophisticated ancillary guidance devices are being designed; these will simplify the performance of CT-, ultrasound-, and MRI-guided procedures (see Fig. 61-7). One device recently introduced by Magnusson et al²⁵⁹ shows great promise for the future. Other mechanical and light-guided devices are being developed.

Additional new techniques will be developed and refined for the percutaneous treatments of tumors and also insertion of physiologic monitoring or activating devices. The first examples of *in vivo* tumor treatment using ethanol injections have been reported; these are described in this chapter. Physiologic monitoring devices such as thermistors for hyperthermia and pressure transducers for tumor treatment will follow in the near future. Also, it is probable that insertion of electrodes for stimulation of various muscles will come into common usage.

The 1990s

Several significant changes occurred in the 1990s in routine procedures, relative to devices used and new ap-

proaches to assist in percutaneous procedures. In the type of needles used, the cutting needle has become ubiquitous and used in virtually all circumstances. It is somewhat strange, looking back at the early days of interventional, that it took two intense years of reviews and negotiations to get our first paper on lung biopsies and cutting needles by Goralnic et al¹²⁰ published, and now such procedures are extremely commonplace. Relative to cutting needles in general, a recent survey by Mayoral and Lewis showed that 95% of liver biopsies were performed by cutting needle "guns."²⁶⁶

The treatment of tumors has progressed rapidly. While in the earlier edition of this text, the first cases of alcohol treatment were just being performed, these procedures have become common and are performed everywhere. Ironically, this area has progressed so rapidly that the technique came into vogue, was developed and refined, and now is relegated into a secondary role already by radiofrequency ablation. We are now in the rapid phase of refining those methods and have progressed from simple radiofrequency ablation to that of combined therapy, which is described in that section.

Methods of instrument localization and guidance have been refined and have progressed remarkably. Our lament in our earlier editions about the lack of attention to the interventions by vendors has now been answered. Numerous improvements in equipment have occurred to simplify and facilitate CT- and MRI-guided procedures. These have ranged from special changes in the equipment to provide faster scans, scans on demand with the operator in the room, new localization devices, and even early experiments into robotic-assisted procedures.

Hemostasis control has also progressed, as discussed in the appropriate sections. New methods and devices have been developed and introduced.

Historical Perspective of Organ Procedures

Lung

The first experience using skinny needles with image-intensification guidance in the lung was reported by Dahlgren⁶⁶ and Nordenstrom³⁰⁴ in 1965. After their report, their results were confirmed by a number of authors using a variety of guidance methods and small-caliber needles. Another early group, Sargeant et al,³⁴⁷ performed biopsies without image intensification with good results. Once image intensification became standard, many authors, including Lauby,²³² Lalli,²²⁶ Westcott,⁴⁰² and Sinner³⁵⁶ reported their series. Many important observations were made about different factors that alter diagnostic accuracy and complications, which will be discussed in the following section on lung procedures.

One fascinating fact that is apparent from reports of these authors is that many different calibers of needles have been called "skinny" needles. Regardless of the caliber of the needle used by the authors (e.g., Lalli et al²²⁶ used an 18-gauge needle, and Zornoza⁴²⁰ used a 23-gauge needle, the diagnostic accuracy was quite good, and the complication rate was quite acceptable.

In the recent literature, the most important article of which is the one by Khouri et al,²¹⁴ it is clear that needle caliber has almost no impact on pneumothorax rate but has a definite impact on hemoptysis. The incidence of pneumothorax is almost identical with all sizes of needles but Khouri et al²¹⁴ reported that the incidence of hemoptysis is greater with needles larger than 20 gauge than the rate of 20 gauge or less.

Further progress for sampling the lung and mediastinum occurred with the introduction of CT procedures in 1976 by my group.¹³⁷ While fluoroscopy has continued to be the main modality for biopsy of the peripheral, well-defined lung nodule, CT provided new advantages for the lung and mediastinum. With CT it became possible to biopsy more difficult lung lesions, to biopsy the mediastinum, and to use the cutting needle safely in selected cases.

Liver

Although Lundquist showed the usefulness of blind skinny-needle biopsies, guided biopsy of the liver with the skinny needle was infrequent until the introduction of ultrasound and CT scanning. The first ultrasound biopsy of the liver was performed by Rasmussen et al.³³⁶ Their study noted the increased diagnostic yield of ultrasound-guided skinny needle biopsy of liver masses, compared with blind Menghini biopsy. The improved yield was of course secondary to the accurate targeting provided by ultrasound. This article is sometimes mistakenly quoted as showing the superiority of the ultrasound-guided skinny needle over the larger cutting needle guided by CT. This article does not even include CT-guided procedures, so any comparison or inference is not valid. Many other authors³⁵³ later confirmed the high accuracy of both the skinny-needle procedure of the liver and the ultrasound guidance. These are noted in the liver section.

After the first CT biopsy of the liver by our group, a large body of experience with both the skinny needle and larger cutting needles has accumulated. Haaga et al,^{144,145} and Ferrucci et al,^{87,89} among others, confirmed that CT-guided skinny needle procedures are quite effective for the diagnosis of many primary and metastatic malignancies. During direct comparisons of the skinny needles and cutting needles, our group confirmed the usefulness of the skinny needle and also noted additional advantages with the larger cutting needles. Currently both ultrasound and CT are used for the performance of biopsies using large cutting needles. For easily visualized lesions, ultrasound guidance is more than adequate, but for more difficult or complicated cases CT is still the modality of choice because of advantages associated with guidance and diagnostic scanning (see later section on liver biopsy).

During this time another researcher, Pagani,³¹⁶ investigated the significance of needle caliber on the diagnostic yield and complication rate of aspiration biopsy of liver masses. With CT techniques he found there was an increased diagnostic yield with the larger needle and no difference in complication rate (see section on needle selection).

Pancreas

Percutaneous skinny-needle biopsy of the pancreas also developed quickly. Before the guided skinny-needle biopsies of the pancreas, some authors evaluated skinny-needle aspirations under direct visualization at surgery. Christoferson⁵³ used the skinny needle in the surgical suite to show that the diagnosis of malignancy could be made with the skinny needle. Forsgren et al⁹³ then used percutaneous skinny-needle aspiration for diagnosis of palpable pancreatic tumors.

With this favorable experience, guided percutaneous pancreatic biopsies of the pancreas were quickly accepted. The first guided percutaneous pancreatic biopsy was performed in 1972 by Oscarson et al,³¹⁴ who used fluoroscopy in conjunction with angiography to localize the needle placement. Although other authors such as Tylen³⁸² used fluoroscopy with contrast studies, the widespread acceptance occurred after the introduction of ultrasound and CT guidance.

Ultrasonic biopsy was first pioneered by Holm et al^{178,179} in 1975. CT-guided biopsy of the pancreas was introduced in 1976 by Haaga and Alfidi.¹³⁸ Both guidance systems have been used successfully, but there are some differences in the methods, accuracy, and complication rates (discussed later).

Impact of Experience

It appears that complication rates with the large or skinny needles are higher with inexperienced persons and lower with experienced ones. If one looks at the reports in the literature, one usually finds an improvement in the authors' results as their reported experience accumulates. Although the skinny needle has a better tolerance for error and inexperienced individuals can use it with few problems, even the complication rates improve. The improvement of diagnostic accuracy with experience was documented by Evander,⁸¹ Zornoza,⁴²⁴ and Hopper.²⁵⁵

CT and MRI Procedures

CT Advantages

CT uses a beam of radiation to penetrate virtually all natural and artificial materials within the human body. Information concerning attenuation of these substances can be measured, and an image can be reconstructed. Because of the wide latitude of imaging capabilities, an extremely low-density material such as gas can be imaged as well as high-density materials such as metal, bone, or synthetic catheters (Fig. 61-5). In addition, CT is sensitive enough to detect subtle abnormalities such as fluid densities, cysts, or small pockets of gas.^{156,157}

The ability to image high-density material accurately offers wide versatility, so that any type of instrument (i.e., needle, drainage tube, or other device) may be used in a procedure. Moreover, contrast material can be injected when vascularity, an anatomic space, or an abnormal cavity needs further delineation. For example, an abscess can have unpredictable serpiginous tracts or communicating

Figure 61-5. Patients with drainage catheters, high-density metallic material, and surface wounds are still suited for CT procedures. This scan shows aspirator of an abscess in a patient with surgical drains (*long arrow*) and skin defects (*small arrow*). Although the scan is not of superior quality, the visualization of the wire (*curved arrow*) used to insert a drain in the abscess is quite easily accomplished.

channels that can be difficult to perceive unless contrast material is used, (Fig. 61-6).

Because the CT unit uses an air interface, it consistently provides a detailed and complete image in virtually all patients. In patients who have draining sinuses, wounds, ileostomies, scars, or other unusual surface problems, the examination can be performed without difficulty.

Another advantage is that the longitudinal scan (Topogram, Scoutview) that I originated¹⁵² is now available on all CT scanners, making it possible to obtain conventional radiographs of the anatomy and to visualize instruments or catheters during insertion or manipulation.

MRI Advantages

MRI advantages relate to its superior ability to image and display subtle qualities related to molecular characteristics. In its earliest and current iterations, it essentially means that proton characteristics are demonstrated within the context of anatomy. This is quite unique because CT shows solely the density or electron density of tissues. MRI is incapable of showing subtle variations within tissues, which may reflect slight variations in tissue characteristics such as viable tumor, slight inflammation, or differences in tissue relaxation that may reflect intralesional detail not detected by CT.

The concrete examples of these properties are the ability of MRI to visualize some subtle pathologies in disease processes (Fig. 61-7). Those details are found in those specific chapters, but several areas are worthy of mentioning in this chapter. In the pancreas, MRI is remarkably superior to CT for the detection of subtle islet cell tumors and the details of some cystic tumors of the pancreas. From an anatomic resolution perspective CT is superior, but with these tumors molecular qualities related to their molecular properties make MRI superior for detection or characterization. It is not illogical to assume that in the future, these qualities will be exploited by future interventional strategies, most likely therapeutic approaches.

Also because of these qualities MRI is well-suited to follow the progress of the treatment procedures. It has been well-documented that MRI is the most accurate for displaying the tissue changes from radiofrequency treatment. Experimentally it has even been able to display characteristics correlating with absolute tissue temperature. With the current emphasis on treatment, it may also be possible with higher field magnets with broadband capabilities to visualize drugs in situ as they circulate within the tissues and the target molecular sites.

Another advantage of MRI imaging is its ability to image blood vessels and also to assess vascularity as it relates to general blood flow. MRI during standard pulsing sequences shows vessels even without contrast material. Moderate-size vessels are clearly seen as a flow void.

Figure 61-6. A, Patient with Crohn's disease and abscess. Scan shows a needle being inserted in the abdominal wall abscess as well as a subtle air-filled fistula between the colon and the abscess. Visualization permitted placement of the catheter adjacent to the fistula to improve drainage and resolution. B, Repeat scan shows a catheter close to the fistula into the bowel.

Figure 61-7. A, CT scan shows a very subtle lesion on an unenhanced scan. Because of the proximity of vessels and poor visibility, it was decided to biopsy the mass under MRI. B, T1-weighted scan shows a subtle mass in the mid-right lobe of the liver. C, T2-weighted scan shows increased signal in the lesion, which was biopsied under MR guidance and proved to be metastatic cholangiocarcinoma.

Although the anatomic spatial resolution of MRI is less than CT, it can also display general tissue blood flow as one might see in hemangiomas but administering gadolinium as a bolus injection. An indirect advantage is also that gadolinium, unlike iodinated contrast material, has a much lower idiosyncratic rate, so that patients who are allergic to traditional contrast material used with CT can be imaged and evaluated by MRI flow studies.

CT Accuracy of Localization

The potential accuracy of the CT-guided method can best be appreciated by examining a schematic drawing of a cross-sectional image (see Fig. 61-3). If the instrument is placed within an anatomic area and the CT scan shows the needle in that area, then the needle must lie within the 10-mm section of the abdomen corresponding to the CT section. Location of an instrument in this plane is limited by the section thickness, which is 10 mm; therefore the resolution in the *z* axis is ± 5 mm. If one uses narrower slices, such as 5 mm, the accuracy in the *y-z* plane is ± 2.5 mm. Resolution of the CT system in the *x-y* plane is less than 1 mm with modern scanners. The precision required in determining the position of such an instrument is less limited by the imaging equipment than it is by the degree of the operator's accuracy, as determined by manual dexterity and by the degree of accuracy of the guidance system rather than the imaging equipment.

The ability to localize the needle tip consistently and accurately in an axial plane is a distinct advantage of CT over fluoroscopy or ultrasound. Although fluoroscopy can provide multiplanar visualization of a needle or instrument, it is not capable of directly visualizing soft tissue abnormalities, except in the chest. Fluoroscopic localization of instruments depend on indirect information obtained from displacement of contrast-filled structures (e.g., bowel, biliary).

The special advantage of CT guidance is that visualization of the needle is an absolute forgone conclusion and does not require special technical approaches or concerted efforts to visualize the needle. These simple facts make this technique adaptable to virtually any environment so that even radiologists without special MR skills can master this guidance method. Unfortunately, MRI procedures require special expertise and also low-field magnets to effectively perform invasive procedures. Talented MRI physicians are adept and skillful at the use of MRI, but the average physician has some difficulty (see MR section). Fluoroscopy is ill suited because it does not provide three-dimensional relationships required for most accurate procedures.

MRI Accuracy of Localization

The accuracy of MRI localization is somewhat more complicated to discuss than CT localization. MRI is very

Figure 61-8. A, These two sets of images show the importance of properly orienting the readout gradient to the alignment of the needles. This image shows various size needles within an apple with the gradient parallel to the needles. Note how visualization of the needles is lessened by the apparent thin diameters of the needles. B, This set of images of the same needles in the same apple shows the diameter of the needles as being very large, enhancing their visualization. With the gradient perpendicular to the orientation of the needles, the localization of the needle tip is more accurate than with the gradient parallel. This was well demonstrated by Lewin et al.²⁴⁰

accurate at displaying general anatomy and precise molecular proton qualities. This makes it suitable to see pathology well, but displaying the needle or instrument is more involved. In selected cases MRI is indicated because the lesions are more clearly visualized on MRI than CT (Fig. 61-8).

Because most instruments are made of a metal that is a major component of steel, the ferromagnetic properties dictated that special materials be used for such procedures. One should use instruments specifically designed for MR usage, because standard needles can become mobile within the magnetic field.

Low-field magnets with open access are required for optimal performance of such procedures. Seminal work by Lewin et al²⁴⁰ evaluated the merits of high- and low-field magnets for procedures and determined quite definitively that low-field magnets were best suited. In this paper, Lewin et al²⁴⁰ reported the importance of using frequency encoding axis perpendicular to the needle shaft. This provides the most accurate visualization of the needle because it artifactually widens the image of the needle, making it more visible in the tissues and more accurately displaying the needle tip (see Fig. 61-8). Gradient-echo imaging is the preferred pulsing sequence because it increases the apparent width of the needle, improving its visualization but not large enough to preclude accurate needle-tip localization. Because of the rapid scan times of the gradient-echo sequences, they almost permit near real-time monitoring during needle insertion.

Ultrasound is useful for the diagnosis and visualization of soft tissue abnormalities, and in some cases it can provide localization of instruments.^{58,178} It is somewhat less flexible for such procedures because visualization can be impaired by overlying gas and bone and thus requires

“windows” for accurate imaging. Because of the reflective properties of a needle, it can be seen “breaking” the beam and providing some general localization; precise localization of the tip, however, is not always easy. This is not a significant problem because one can wiggle the needle and improve its visualization by movement of the tissues. The visualization can be optimized if the needle can be inserted at a right angle to the beam, but this is not always convenient or appropriate in many patients.

There are several innovations with ultrasound³⁰⁹ that may potentially improve the visualization of the needle tip. One company has recently introduced a needle that transmits an ultrasound signal audible to the transducer. Others have suggested that with the exquisite sensitivity of color-flow Doppler for motion, better visualization of the needle is possible.

Recently, several authors introduced the possibility of using MRI to perform biopsies. Mueller et al²⁹⁴ have done some promising preliminary work with various types of stainless steel instruments. Although in theory MRI-guided biopsies are appealing, there are technical problems because of the physical configuration of current devices, spatial fidelity of current devices and the difficulty in the clinical monitoring of such patients.

Although almost all reports confirm the advantages of CT, there is still occasional controversy on occasion concerning which modality should be used in which circumstance. In practical terms the individual radiologist must determine the degree of accuracy, confidence level, and role for CT, ultrasound, and MRI.

Versatility

Versatility is still one of the most valuable advantages of CT-guided procedures. Since the skin is unimpeded,

no “holding” devices are required. There is significant versatility in selecting the entry point for the biopsies because of the completeness of the CT image: A full 360-degree view of the patient is provided. All organs, including the bowel, are visualized, so that a variety of needle pathways can be chosen. It is possible to choose appropriate pathways to avoid specific organs or the bowel, if clinically indicated. Changing the body position of the patient may be advantageous for opening windows for instruments because of organ shifting or patient comfort (changing positions creates no adverse effect on image quality). Finally, a wide variety of instruments can be used, ranging in size from a 23-gauge Chiba needle to a 14-gauge Tru-Cut needle. Of all of the advantages of CT procedures, versatility is the one that is least recognized.

Versatility in being able to approach the patient in any angle or body position is extremely useful. As noted in the later clinical sections, three major benefits are derived. First, if patients are going to cooperate during a procedure, it is critical that they are comfortable on the table. Patients with back pain or localized discomfort in the flank can be induced to remain still during a procedure if they can become comfortable by shifting their position. Permitting the patient to lie in a prone, lateral, or oblique position can go a long way to improving patient comfort, cooperation, and therefore success of the procedure. The second benefit of moving patients into different positions is that the internal anatomy shifts accordingly and permits better and safer trajectory planning and execution. In the abdomen, bowel and organs shift sufficiently to permit a safer sampling

procedure. In the chest, lesions in the anterior mediastinum can be more safely sampled because laying them on their side may shift the anterior junction line sufficiently to permit a pathway avoiding the lung parenchyma (Fig. 61–9). Third, in some cases when a patient has control taking consistent breaths and the lesion is quite mobile, placing the patient in a lateral or oblique position can be helpful in limiting the movement of the lesion. When the ipsilateral side of the patient is dependent, the weight of the viscera partially immobilizes the diaphragm and limits the movement of the lesion.

It is indeed perplexing that some radiologists do not change the patient position or trajectory of the needle to avoid uninvolved structures. For example, instead of approaching retroperitoneal lesions posteriorly through the flank, they use only a direct anterior approach to traverse bowel or other organs. As noted in the sections on organs, especially adrenal, pancreas, and others, traversing an uninvolved organ can produce significant complications.

MRI is also versatile based mainly on its ability to display coronal and sagittal planes in quick scanning sequences. This permits more convenient angulation of devices and trajectory planning when lesions are high under the diaphragm. Also, because of the flow void phenomenon, blood vessels are easily visualized as structures void of signal. There are some limitations related to the short distance between the coils in an interventional device. This creates some problems with long instruments, but they can usually be resolved by patient positioning and approaches unless the very largest patients are encountered.

Figure 61–9. A, Scan shows a subtle mass in the anterior mediastinum, thought to be thymus, but the clinical situation dictated that a biopsy be performed. The anterior junction line is concealed behind the sternum. The only possible biopsy approach would be a very lateral one traversing much lung parenchyma. B, With the patient lying on the right side, the mediastinum shifted so that a clear access to the mass without crossing the lung was provided.

Disadvantages of CT Guidance

CT guidance has a number of apparent disadvantages that are quite minimal in comparison to its advantages. Those to be considered include cost, radiation, and availability of equipment.

Although it is true that the cost is greater than for other examinations, the cost savings of a CT biopsy compared to alternative costs of surgery and/or hospitalization are remarkable. Mitty et al²⁸¹ calculated a savings for CT-guided pancreatic biopsies of more than \$3000 per case. Considering that more than half of all such biopsies are performed on an outpatient basis, the savings is actually more than that amount. By comparison, ultrasound is much cheaper but MRI is much more expensive.

The CT scan obviously uses radiation for generation of the scans, but the dose delivered to the patient is much less than other specialized studies such as angiography. With modern scanning devices, doses for individual scans can be calibrated to lessen these exposures.

In the recent generation of scanning devices, as a result of increased awareness about radiation safety, vendors are finally producing "photo-timed" CT scanners. The detector systems are being utilized in conjunction with the computers to measure the dosage "on the fly" so that optimization of dosage occurs even within the context of a specific scan. I cannot avoid the opportunity to say "I told you so and it's about time," noting this was proposed many years ago in our second edition of the textbook.

Disadvantages of MRI Guidance

The major disadvantage of MRI guidance is that visualization of instruments and anatomy is dependent on operator technical skills. Small-field magnets are required to ensure access to the patient so the appropriate technical sequences of the device are critical as well as the experience of the radiologists. In practical terms, interventionalists must be experts in the field of MRI so that they can alter the sequences during the procedure to maximize lesion resolution and minimize artifacts of the instrument visualization. An average radiologist does not have the skills to routinely perform such procedures.

A practical disadvantage that results from these facts is that MRI procedures are seldom time-efficient. Procedures typically require considerably longer than an hour. Even in experienced centers, seldom are more than three or four procedures performed during an 8-hour period. On the other hand it is not uncommon for experienced CT sites to perform four to nine procedures per 8-hour day.

Future of Combined-Modality Imaging

In recent years, devices have been built that combine positron-emission tomography (PET) and CT devices within the same piece of hardware. As one might expect, these devices offer great potential for enhancement of interventional procedures. The functional aspects of PET should permit better visualization of active pathology within the immediate context and milieu of the interventional procedures.

One must recall, however, that these devices are not designed for enhanced patient throughput. PET scans still require considerable time for collection of data to ensure appropriate signal-to-noise ratio.

It must also be noted that modern computer techniques permit fusion of functional PET images with CT images. These techniques use standard imaging devices already in existence, and clinical practice can answer most queries related to activity and anatomy.

For the devices to become widely accepted, their role with interventional procedures must be better defined and developed. There is little question that the emphasis on image-guided local treatment of neoplasm will continue to improve and evolve.

It is my opinion that within this context, these new devices will come into wide usage only if their role with interventions can be developed and defined.

Indications for CT-Guided Procedures

The indications for CT-guided procedures vary from institution to institution, depending on the expertise of the radiologists and the available imaging modalities. Generally, the important factors to consider are the visibility of the lesion on CT as compared to other modalities, the type of pathologic sample required, and the location of the lesion.

Considering that the prime function of the guidance modality is to direct the needle to the lesion, visibility of the lesion is the most obvious factor. Plainly stated, if one cannot see the lesion, one cannot biopsy the lesion. Therefore, if a lesion is seen only on CT or much better on CT, then CT is the modality of choice. Likewise, if a lesion is seen only on ultrasound or MRI, then they are the preferred guidance methods.

When an aspiration type of biopsy is clinically indicated, a variety of factors should be considered. As a rule, the simplest modality that satisfactorily shows the abnormality, pathway of the instrument, and adjacent anatomic information should be used. Generally, anatomic areas such as the retroperitoneum and pelvis are in most instances best suited for CT guidance. Specific consideration of each anatomic area are discussed later.

When lesions are small (ranging from 3 to 5 cm) and are located in critical areas, CT is again the preferred modality (Figs. 61-10 and 61-11). Critical areas best suited for CT punctures include abnormalities adjacent to major vessels, the hilum of the spleen, and the mediastinum. Certainly, visualization of such small lesions may be first attempted using other modalities (but most authors agree that successful punctures on the first attempt are more likely with CT guidance). Any procedure that fails with other modalities should be attempted using CT.

CT should be used when avoidance of intestinal loops or vascular structures is important (Figs. 61-11 and 61-12). We believe such avoidance is advisable in several situations. In immunologically compromised patients, we believe that CT procedures should be used to avoid penetration of the bowel and possible contamination (even with the skinny needle). Even in immunocompetent patients, if the abnormality to be punctured is a fluid density, we

Figure 61-10. A, Scans adjacent to a mass (M) in the tail of the pancreas shows the close proximity of varices (arrows) in the gastrosplenic ligament. B, With the patient in an oblique position and angled approached, aspiration needle biopsy (arrow) of pancreatic mass avoiding the colon, spleen, and varices was accomplished. Unlike other authors who commend traversing uninvolved organs, I recommend at least an attempt at avoiding them. In most cases, penetration can be avoided. Over a large series of procedures, the absolute number of complications will be less because at least a relatively smaller number of inadvertent penetrations will occur.

Figure 61-11. A, Small lesions in deep locations can only be sampled using CT. Scan shows a tiny mass in the root of the mesentery. This first pass shows the needle (arrow) deflecting past the mass. Note that the patient was positioned obliquely, which permitted the bowel to float away slightly, thereby clearing a pathway for the needle. B, Repositioning of the needle and using the bevel of the needle to prevent deflection, the mass was sampled adequately. See section on needle deflection.

Figure 61-12. Lymph nodes adjacent to aorta are only suited for CT guidance because of the accuracy required.

believe penetration of the bowel should be avoided (see section on pyogenic contamination). A variety of approaches can be used to avoid bowel because the bowel can be seen and patient position can be varied (see Fig. 61-11). A recent advance (discussed later) has been the use of carbon dioxide or other gas to move various loops of bowel.

When a large cutting-needle biopsy is clinically indicated, CT is usually the modality of choice. Even though fluoroscopy or ultrasound can be used safely in many cases, CT is the best guidance modality because it eliminates the two most likely errors: (1) inappropriate biopsy of uninvolved organs (e.g., gallbladder, vessels) and (2) inappropriate biopsy of abnormalities with increased vascularity. The accurate display of abnormalities as well as any normal structures that may be displaced prevents inadvertent puncture. Bolus dynamic scanning is accepted by virtually all authors as being highly accurate for the assessment of vascularity (Fig. 61-13), whether in the liver or other areas. It is as accurate as digital subtraction because both use the same detector principles and computer enhancement.

CT may also be a modality of choice when some type of contrast agent such as urographic contrast or air is to be injected. Such contrast can provide additional information about cysts, abscess, pseudocysts, or dissemination of medication.

Indications for MRI Procedures

The primary indications for MR procedures are basically (1) superior visualization of abnormalities on MRI and (2) the need to watch tissue changes during ablative procedures, either chemical or radiofrequency heating. Some subtle abnormalities in the liver or kidney are not well seen with CT or ultrasound and are best seen on MRI. Depending on the lesion being ablated, it may be critical to follow the heating changes to ensure that complete destruction of the lesion occurs or to monitor potential inadvertent damage to uninvolved structures.

General Complications of Procedures

A number of possible complications are specific to the various organ systems, but some general concepts are relevant to all areas. Because of the advantages of CT procedures the possibilities of complications are significantly reduced. If proper CT techniques are used, the major causes of complications are limited to poor technique, lack of patient cooperation, undetected coagulopathy, or undiagnosed obstructive or diffuse interstitial processes in the lung.

Before discussing in detail how one can avoid certain problems, several comments should be made concerning complications as they relate to the two major categories of instruments: the aspirating, or skinny needle and the large cutting needles. Contrary to the opinions of others, severe complications may occur with any needle (including the skinny needle, manual cutting needles, or the automated biopsy guns) unless one exercises caution, common sense, and meticulous technique.

Figure 61-13. A, Noncontrast scan of a veteran sent to our institution for a “lymph node (M)” biopsy. The large mass to the right of vena cava was thought to be a lymphoma mass; a 14-gauge cutting needle was ordered. B, As dictated by our protocol, a bolus dynamic scan was performed that showed a large enhancing varix (BV) fed by smaller varices (v) in the right lower quadrant. Biopsy was not performed. C, Digital subtraction image shows large tubular varix (arrows) flowing toward the liver.

Skinny-Needle Complications

There is no question that the skinny needle is the safest instrument available, but even this needle can produce complications in selected circumstances. For example, one can find in a careful review of reports of skinny-needle biopsies of the pancreas instances of pancreatitis, pancreatic fistula, cholangitis, needle-tract seeding, significant hemorrhage, abscess formation, and fatal pancreatitis. An awareness of these potential problems should not be a deterrent to performing such procedures but instead should be an incentive to eliminate complications, even with the skinny needle.

Most complications have occurred with skinny needles when lesions have been highly vascular or numerous needle passes have been made. The reported fatalities from liver and adrenal hemorrhage occurred with apparently vascular hemangioma and pheochromocytoma. One can see in reviewing the literature that most complications have occurred in those cases with four or five needle passes.

This viewpoint about limiting the number of passes and minimizing risks even with skinny needles is shared by another expert interventionist, Dr. Ed Smith of the University of Massachusetts.³⁹⁰ Dr. Smith, in his recent chapter on the risk of fine-needle biopsy, reported on the results of a survey mailed to 100 university hospitals and every fifth hospital with more than 200 beds. In this survey he noted the occurrence of 4 deaths, 27 cases of hemorrhage, 3 occurrences of needle-tract seeding, and 16 cases of generalized infections (nonfatal). In his conclusion Dr. Smith made a statement with which I concur completely.

It is logical to assume that the number of complications should be related to the number of needle passes made during the

biopsy procedure. However, serious and even fatal complications, although rare, can and do occur and it is important to be aware of the possibility and take all the appropriate precautions in order to reduce their incidence.

Cutting-Needle Complications

With large needles one obviously has a greater probability of incurring possible complications because a large “hole” is being produced. It is quite apparent however, that by using meticulous technique, the potential risks of these needles can be offset and very low complication rates can be achieved.

A recent alarming trend in regard to the large needles is that some authors who advocate their use have become somewhat “cavalier” about potential complications. One must pay careful attention to meticulous technique or serious and even fatal complications will result. Indeed, it is likely that in the near future, unnecessary and serious complications related to the large needles will be reported. It is my hope that individuals who are now starting to use these needles will seriously adhere to the cautionary advice of experienced interventionists.

It is especially important to note that the new automated cutting devices are no safer than the standard Tru-Cut needle that has been used for many years. The speed of cutting has no effect on the local damage produced to tissue and thereby the potential risk from such a procedure. In the first report about the biopsy gun, the authors described a serious hemorrhagic complication following a liver biopsy. Potential problems are minimized by CT guidance and a careful, meticulous technique such as I have

described. These measures can eliminate many potential causes of complications (e.g., hemorrhage or inadvertent penetration of an uninvolved organ) and can result in excellent accuracy with few problems.

Avoidance of Uninvolved Structures

A major determinant of complications is the penetration of uninvolved structures. With the spectacular imaging characteristic of CT, intentional penetration of adjacent structures is inexcusable if other clear pathways are readily available. There are numerous articles in the literature that proselytize using a trajectory through an adjacent structure such as pancreas or liver during an adrenal biopsy, bowel during a pancreas biopsy, aorta or vena cava for pancreatic procedures, spleen during pancreas biopsy, and pleura during an abdominal procedure. The facts are such advocates are promoting sloppy, ill-advised techniques.

It is of course unavoidable that penetration of such structures may occur during an attempt of a meticulous and appropriately planned technique. The point is that complications may occur on a statistical basis. The fewer times one penetrates an avoidable structure, the lower the long-term complication rate. For example, if one chooses to penetrate the aorta or venous structure during a celiac nerve block, there will be a well-defined rate of complication. It may be the rate will be less than 5% of 100 cases. If one intentionally uses this approach, the operator will have five complications when they have accumulated 100 cases. If one tries to avoid these vessels, inadvertent penetration may occur in 10 of 100. It may be that the involved radiologists might never have the five complications, because it statistically will take a total number of 1000 cases before 100 penetrations occur.

The reasons to avoid such approaches are for legal reasons and also the future of the field. Legally the more complications, the greater the chance of lawsuit and monetary damages. The other reason is that we should develop meticulous techniques to advance the field. The average radiologists who read this chapter may think the procedures I show are not possible for them to learn. The fact is that every time operators perform a meticulous technique avoiding other structures, they are learning the methods to

advance their skills, such as we are demonstrating in the mediastinum, pancreas, and other organs.

"Crap Happens"

It is quite obvious that complications may occur even if no error was made (Fig. 61–14). This was the subject of the article published by Dr. Yohan and our group called "Complications of No Biopsy."⁴¹³ Recognizing these can occur randomly on occasion, we should avoid approaches with a higher incidence of complications.

Hemorrhage

The most likely potential risk during any biopsy procedure is the occurrence of bleeding. The vascularity of the pathologic lesion as well as the anatomy, occurrence rate, and risk of bleeding are specific for each organ system, these factors are discussed in relation to each organ system. For example, highly vascular lesions of the liver such as hepatomas, sarcomas or hemangiomas¹⁷³ potentially have a high incidence of serious hemorrhage unless meticulous methods are used. Generalized statistics that combine rates for multiple organ systems (e.g., liver, pancreas, lung) are not relevant to the modern approach to biopsies.

Obviously, to avoid complications one must ensure that a patient does not have any bleeding coagulopathy and the laboratory values are within acceptable ranges. Several animal studies by our group^{102,104,105} evaluated the effect of needle caliber, type, prothrombin time, and platelet counts. In those studies platelet function appeared to be even a more important factor than prothrombin time. With either abnormal platelets or prothrombin time, it was shown that there was a considerable difference between needles smaller than 16 gauge and those larger than 16 gauge. I prefer that the prothrombin time be within 2 seconds of normal, with the partial prothrombin time within 25% of normal, and the platelet count be greater than 50,000. In some critical clinical circumstances exceptions can be made, but with such variances the potential risk is greater. The attendant risks and associated precautions should be understood by all involved (patient and physicians) and appropriate contingencies made.

Figure 61–14. A, Scan shows thickening of the gastric pull through segment, believed to represent tumor. Based on this study, I scheduled the patient for a biopsy procedure. B, Repeat scan on the day of the procedure shows a normal-appearing stomach, so the procedure was canceled. There was no skin preparation or local anesthetic. The patient was admitted to a local hospital the next day with life-threatening hemoptysis. She ultimately died from bleeding. See section on "Crap Happens."

Patient Cooperation

One cause of complications common to all procedures and not eliminated by CT is lack of patient cooperation. If a patient moves or cannot suspend respiration at the appropriate time, difficulties may arise. The most critical factor to enhance patient cooperation is adequate local anesthesia in the area of the biopsy. Local anesthesia should be administered down to the serosal surface of the organ (e.g., pleura, capsule). If this area is not anesthetized, the patient may "jerk" at the time of insertion and produce a tear, bleed, or pneumothorax.

The other factor that has been alluded to and is critical is patient comfort on the table. The patient should be positioned in whatever position is the most comfortable within the context of the anatomic trajectory. This must be specific to the patient and may include pillows under the knees, shoulders, and so forth. If patients must lie immobile, they may fidget if they are uncomfortable.

For those patients who are emotionally upset, administration of an appropriate hypnotic or sedative can be quite helpful. Dosages of such drugs vary widely, and local sedation policies should be followed.

Pyogenic Contamination

Contamination of sterile areas is possible from either a cutaneous source or, if a loop of bowel is penetrated, an enteric source. If Betadine is used for preparation of the skin, cutaneous contamination is improbable. Contamination from bowel can occur, depending on the immune status of the patient, the nature of the abnormality, the size of the pyogenic inoculum, and the virulence of the pathogens. Interventionists who advocate traversing bowel with impunity should be regarded with a slight amount of skepticism.

It is true that an immunocompetent patient can tolerate spillage of a small amount of bacteria within the peritoneum, but the clearance of bacteria is impaired in certain circumstances. If bacteria are introduced into a fluid space, experimental data shows that the effectiveness of bacterial "killing" is impaired because (1) opsonization of pyogens by antibodies and complement is less efficient in a fluid space, and (2) phagocyte-clearing activity is impaired in a fluid space based on physical spatial considerations and the probabilities of random particle encounters.⁴⁰⁹ Moreover, an immunocompromised patient is obviously at a greater risk from pyogenic organisms because of the reduced number or function of immunologic cells.²²⁶

This concern about bacterial contamination from percutaneous procedures is well-founded. A number of secondary infections have occurred and been reported in the literature. One reported case of peritonitis was produced in an elderly woman after penetration of the colon by a skinny needle during a lymph node biopsy.³⁵⁸ In his survey Smith accumulated 16 cases of generalized bacteremia occurring from aspiration biopsy in the survey that were treated by antibiotics.³⁵⁸

For these reasons I modify my technique in several circumstances to eliminate or lessen any potential risk of bacterial contamination. If the mass is solid in an immuno-

competent patient, I will accept a trajectory crossing bowel; a small inoculum of bacteria is no match for the normal immune system. (Practically speaking, it is difficult to penetrate bowel unless one tries because it will move away from the needle). If the lesion being sampled is cystic, I insist on avoidance of bowel for the reasons stated earlier. Passage through bowel also would be counterproductive for the culture of cystic masses because of possible spurious results from contamination.

If the patient is known to be immunocompromised, I will avoid traversing colon or small bowel in all cases. In such cases I usually prefer to cancel the procedure rather than to put the patient at risk.

Avoidance of bowel in any of the cases noted earlier can usually be achieved by changing the position of the patient, which may result in "shifting" of the bowel that may open clear pathways for needle insertion (see Fig. 61-11). In other cases, injection of carbon dioxide may be used to move bowel loops (see section on tissue retraction and movement).

Vasovagal and Hysterical Reactions

Interventionists not familiar with vasovagal or hysterical reactions cannot diagnose or properly treat them. Both of these events, which are relatively common, must be dealt with properly and expeditiously to prevent physiologic sequelae or inappropriate iatrogenic intervention.

The vasovagal reaction is a sudden discharge of the parasympathetic vagal nerve, resulting in bradycardia, vasodilation, and hypotension. Such patients appear pale and ashen gray and may be partially responsive or unresponsive. The appearance is not unlike that of a patient who has had a cardiopulmonary arrest. Close inspection of the patient will show the presence of bradycardia, diaphoresis, dilated pupils, and hypotension. Treatment of this event should be tailored to the severity of the situation. The patient should first be put in a Trendelenburg position to enhance venous return to the heart and cerebral blood flow. Do not sit the patient upright—the hypotension will be worsened. If the patient improves within 1 to 2 minutes, no other action need be taken.

However, if the patient does not improve quickly, oxygen should be administered by nasal cannula and an appropriate dose of atropine, either intramuscularly or intravenously, should be administered. Before administration of the drug, a quick review of the patient's clinical notes is appropriate, patients with cardiac arrhythmias may be quite sensitive to the drug. A single intravenous dose of 0.5 or 1 mg will usually restore the normal heart rate. If the patient's condition persists (i.e., if the atropine does not improve the situation), urgent consultation with a resuscitation team is appropriate. Such patients, especially the elderly, can develop a complete heart block, vascular collapse, and cardiac arrest if not properly treated.

The other event, which is more spectacular but fortunately less dangerous, is a hysterical reaction. Such patients appear agitated, tremulous, and may be crying. Close inspection of the patient may demonstrate tachycardia and systolic hypertension, the pupils will be normal size or smaller. Such patients may be breathing fast and complain

of subjective shortness of breath. After auscultation of the chest confirms good air exchange, the best treatment of such patients is to have them breathe into their hands or into a bag to prevent hyperventilation and subsequent fainting. If hyperventilation occurs, the patient may become alkalotic and faint because of constriction of the cerebral vessels. The next step is to give the patient gentle but firm reassurance; if there is no response, the patient should be removed from the biopsy suite. Before any repeat attempt, the patient should receive an appropriate sedative. Careful assessment of all biopsy patients during the informed consent period usually indicates those who need sedation, thereby preventing any such hysterical reactions.

Tumor Recurrence in Needle Pathway

Growth of residual tumor cells tracked through needle pathways has been a minimal problem in the past but potentially will be a larger problem in the future. The potential for more problems stems from the fact that more procedures are being performed throughout the world, so the absolute numbers will increase even if the relative occurrence remains low. A guidance cannula in the skin stops tracking in the skin, but of course this does not stop any deeper seeding beyond the tip of the cannula. In reality, most tumors are inoperative when they are biopsied, but if there is a possibility of curative resection, a trajectory should be chosen that will permit resection of the needle track by the surgeon.

Although the exact reason why tumor implants occur is not known, it is clear there are two main factors affecting the outcome: type of tumor and the implant site milieu. The best example to appreciate this is with breast cancer. This is ideally suited because I personally have not been involved with breast procedures and have no bias to bring to this topic. Several authors, Diaz et al⁷² and Stoller et al,³⁷² have reported on the frequency of tumor cell displacement occurring in tissues after large-needle biopsies and provide significant insights into tumor seeding. Diaz et al⁷² studied a series of 352 cases and looked at the occurrence of tumor cell displacement in specimens that were resected. Diaz et al⁷² found that a greater number of tumor cells were present in a short period after the biopsies than at a later time. This suggests that tumor cells do not survive displacement in usual circumstances in the breast. In the group resected in less than 15 days, 42% had displaced tumor cells present. In the group resected more than 28 days, only 15% had displaced tumor cells. The reason a few residual cells may survive to cause low seeding or recurrence is likely dependent on the type of tumor, general differentiation, immune system of the person, antigenicity of the tumor, and local milieu such as vascular characteristics.

There are five organ systems that should be discussed: lung, kidney, pancreas, musculoskeletal tumors, and liver. In the first four systems, implantation and seeding have not been a problem, but numerous incidents with liver are being reported.

In the lung the question of tracking in the tract is often raised, but occurrences are rare. Indeed, only a few cases of seeding have been reported. Considering the thousands

Figure 61-15. Enlarged view of the chest wall shows a tumor implant (arrow) to the left of the sternum from a previous lung biopsy from an outside hospital. (Courtesy of Dr. Julie Clayman, Cleveland, OH.)

of such procedures performed, the incidence, as noted by Wolinsky,⁴⁰⁸ is very low. We have never encountered a tumor implant in any of our cases, but we have observed one from an outside institution (Fig. 61-15).

Needle tracking of renal tumors is a frequently mentioned potential problem by some colleagues in urology, but it is a very low rate of occurrence. However, I am familiar with only one case of needle tract seeding, reported from the Mason Clinic following aspiration with an 18-gauge needle. However, there is overwhelming evidence that seeding is not a problem with such a tumor. Von Schreeb et al³⁹⁵ reported a controlled series of about 150 cases of proved renal cell carcinoma used to study the impact of needle aspiration. One half of these cases were aspirated and one half were not. There were no instances of needle tract seeding. Furthermore, the difference in recurrence, morbidity, and survival was actually better in the biopsy group.

The pancreas has had a surprisingly frequent rate of tumor seeding compared with the kidney or lung. There have been two reported cases^{88,335} of skin seeding with this pancreas tumor. Considering that there have been only several hundred cases reported in the literature, this is a relatively high frequency compared to the frequency associated with the lung or kidney. Tumor seeding in patients with pancreatic cancer is not a significant clinical problem because they are invariably incurable.

The fourth group of cases that have a possible incidence of seeding is musculoskeletal tumors. Until more experience is gained with percutaneous biopsy of these tumors, one must exercise caution and make a special selection of entry point in collaboration with the orthopedic surgeon. In my practice, I contact the referring orthopedic physician for each procedure to choose an entry point so that the needle pathway can be resected at the time of surgery.

Finally, in recent years a large number of incidental cases of tumor seeding has occurred in patients with hepatocellular carcinoma. Multiple authors (Soyer et al,³⁶⁶ Llovet et al,²⁴⁹ Sato et al,³⁴⁹ Kim et al²¹⁶) have reported this in relation to needle biopsy, tumor ablation, biliary drainage, and even laparoscopic procedures. The increase in reports

is undoubtedly due to the increased frequency of image-guided microsurgery use and minimally invasive surgery as well as the nature of hepatocellular carcinoma.

Preprocedural Steps

Patient History and Consent

Before the procedure and any administration of any medication, it is important to discuss the procedure in depth with the patient. All details, including the rationale, medical alternatives, method of the procedure, sensations to be felt by the patient, and the postprocedural routine, should be mentioned. After this discussion the patient may sign the informed consent form and help confer about the need for any sedation.

During this time, also inquire about any medication that may alter coagulation or platelet function. The latter is especially important because platelet inhibitors are widely used and not described to patients as "blood thinners." Routine coagulation studies do not detect the presence or activity of platelet inhibitors. Laboratory work performed by our group has confirmed the serious alteration and risk of the coagulation status in patients on aspirin-like compounds.

Two of the most troublesome situations are those patients who are being treated with low-molecular-weight heparin and also patients with systemic lupus erythematosus. There is widespread use of low-molecular-weight heparin because it has a much lower incidence of over-anticoagulation than traditional heparin. The problem with this agent from the perspective of interventional procedures is that the methods for assessing the degree of anticoagulation are not readily available at many hospitals. Furthermore, few clinicians are aware of the required test, which is an assessment of factor X inhibitor. Within our community several catastrophic events have occurred in association with this new agent.

The other troublesome clinical scenario has been in those patients with lupus erythematosus. With lupus, there is a high incidence of patients who have spuriously elevated coagulation tests due to unknown circulating antibodies. The dilemma that arises is when such tests are positive, one cannot be sure if the patient will clot normally.

Both of these situations are fraught with difficulty because the attending radiologist, not the referring clinician, bears the brunt of the legal consequences if bleeding occurs. The best approach in these situations or others that might arise is to rely on an older coagulation study—the bleeding test—when available. This test evaluates the time required for a standard puncture site to stop bleeding; as such it actually takes into account all factors, including the intrinsic, extrinsic, and the capillary properties. A substitute for this test for the interventionalist to become accustomed is to carefully observe a small stab wound made at the entrance site for the procedure. A rule of thumb that I use is that the site should not continue bleeding after gentle pressure for several seconds. If the blood continues to flow, one should inspect the site and review the history. Although this is rather arbitrary, this observation is worthwhile and can avoid catastrophe if one becomes accustomed to making this observation.

Sedation and Analgesia

Because of the powerful but effective sedative and analgesic agents now available, one must be conversant with basic life support resuscitation and also the sedation protocols of the home institution. Most institutions now require some type of basic proficiency for sedation administration, so the operators must make sure they comply with institutional, state, and federal guidelines and certification.

Two types of medication may be given to patients: one for sedation and anxiety and another for analgesia. For anxiety, a mild sedative such as midazolam (Versed) should be given. In most average-size adult patients, 1 mg intravenously can be given at the onset and then titrate the needs of the patient during the procedure. As a rule it is probably better to err on the side of giving medication, but if there is no apparent need by the history or from clinical observations of the patient, one should withhold the drugs.

Laboratory Studies

For routine aspiration procedures on a patient with no history of coagulopathy or medication, I request partial thromboplastin time, prothrombin time, and platelet count. If it were not for the litigious environment, I would not even obtain these studies for aspiration biopsies. For patients who are to have cutting biopsies I prefer the platelet count above 50,000, prothrombin time within 2 seconds of normal, and a partial thromboplastin time within 25%. If there is any suspicion of anemia, I order a hematocrit study. I perform aspiration at almost any hematocrit level if the coagulation is normal, but I insist on a value of 32% for any type of cutting biopsy. Because of the demonstrated safety of CT-guided procedures, I no longer type and cross-match a patient for any blood products unless there is some unusual clinical circumstance.

Bedside Assessment of Bleeding Diathesis

Over the years I have developed great confidence in the use of a bedside method for evaluating bleeding propensity as follows. Hemostasis is a complicated process dependent on platelets, blood proteins, capillary fragility, and circulating inhibitors or antibodies. It is well-recognized that the best way to assess clinical bleeding is to use the traditional bleeding test. This consists of making a standard stab wound and measuring the time interval required for local hemostasis. This test is seldom used in modern hospitals because of all of the specific laboratory tests that reflect specific coagulation causes. We do not order this test but use a different permutation at the bedside that I believe is helpful for avoiding possible catastrophe.

After the skin is prepared, I always make a small stab wound at the entrance site of the needle. One can use this site as a "bleeding test." Although I do not time the event, I pay careful attention to the clotting of blood from this site. If bleeding continues to "stream" from the site despite several minutes and "blotting" with gauze, I am always concerned about a bleeding diathesis. In the past I have

been able to recognize patients who have had incorrect laboratory values, inappropriate administration of anticoagulants, and other problems. In such cases I would rather terminate the procedure than create a problem; in such cases the laboratory tests, history, and so forth are reviewed. It is a tragedy that the quality of health care has become so degraded, but the facts of the matter are that physicians and professionals are pressured every day to work faster so that oversights are not an uncommon event.

Coagulopathy

With the wider use of image-guided microsurgery, more patients with suboptimal coagulation status are being sampled and treated with these methods. There are a limited number of clinical articles that deal with this topic. Most authors depend on the standard laboratory values that measure the clotting mechanism. Those most commonly used are prothrombin time, INR, and platelet count.

As most radiologists recognize, there are two different pathways that affect the formation of a clot: the intrinsic and the extrinsic pathways. The purpose of both pathways is to ultimately generate a firm clot containing fibrin at the site of injury, either intravascularly (intrinsic) or extravascularly (extrinsic). The common mechanism is the production of thrombin at the site of injury that causes the polymerization of fibrinogen to fibrin.

Within the vascular system (intrinsic), platelets agglutinate onto any site of injury and release platelet tissue thromboplastin, which begins the thrombosis cascade within the blood, ultimately changing prothrombin to thrombin. Extravascularly, tissue thromboplastin is released by injured tissue, that reacts with plasma proteins to again convert prothrombin to thrombin.

It is important to seek the proper remedy to the demonstrated coagulation problem before performing a procedure. The assumption is that the radiologist has the luxury of time to correct the problem. When a patient has an abnormal prothrombin time, it is most appropriate to give vitamin K and wait several days for the prothrombin to correct itself. When time does not permit waiting for this correction or the correction does not work, then administration of blood products will be required (discussed later).

For an impaired platelet function or low platelet count, two possible approaches can be taken: platelet replacement or the infusion of desmopressin (DDAVP). The dosage and regimen for infusions should be obtained from the local pharmacy. Although the exact mechanism of action is not known, it has been demonstrated over many years that the administration of this medication will improve the adhesiveness of platelets and thereby minimize the probability of hemorrhage. The exact mechanism is not understood, but it is recognized that the medication is typically most effective on the first administration and is less effective when later doses are administered.

Traditional Infusion Replacement

The traditional approach for correction of coagulopathy is to administer intravenous platelets or fresh frozen plasma

over the course of many hours to obtain a systemic improvement of these factors. Replacement platelets restore a sufficient circulating number so that platelet agglutination occurs ($>50,000$ is required). Fresh frozen plasma is administered to restore the prothrombin time to within 2 seconds of normal. Fresh plasma permits this because it replenishes a number of factors such as prothrombin and factors VII, IX, and X, which are produced by the liver and are deficient when liver function is impaired.

The difficulties with the traditional method are several. The most difficult issues are related to obtaining the blood, administering the blood, rechecking the tests, and transporting the patient to the imaging site to perform the procedure. Regardless of the institution, any where in the world, there are always logistical problems.

The problem typically encountered is incomplete correction of the laboratory tests to the desired levels. The causes are quite numerous and can be related to acquisition of blood samples for testing or acquisition of the blood product, administration of the products, repeat laboratory testing, and transport of the patient. If correction has not occurred, then additional blood products must be administered and more delays ensue. With such delays, the patient is seldom ready for the procedure until late in the day or at night, when availability of support staff is least.

To make this approach work, one must be aggressive in ordering the tests and products and keep close oversight of the time issues. Depending on the level of impairment, the exact amount used will vary, but in most cases I use the following protocol: Order a four-pack of fresh frozen plasma, administer three units over several hours. I request a repeat lab test after the third unit but continue to administer the fourth unit following the procedure. In most cases the fourth unit will have been given to the patient when the lab report returns. From the results one can determine if the correction is proceeding as expected or not; if the results are appropriate the patient is transported, if they are not the test is deferred.

The traditional method has obviously been accepted over the many years, but there are some problems with this approach. If patients have cardiovascular compromise, then the multiple units infused may cause cardiac overload and decompensation. In some patients, there may be antibodies or unknown reasons why such products will not correct deficiencies.

Local Infusion of Blood Products

Since the last edition of this textbook was published, we have developed a new technique that has proven worthwhile in a select number of patients. First, one must realize that this is not a Food and Drug Administration (FDA)-approved use of blood products, but under current legal guidelines, a physician can act on the best behalf of a patient in unusual circumstances. If a product is approved for human usage, a licensed physician can use that product for other uses when the benefit to the patient seems to outweigh the risks. Under these guidelines, a physician can use the technique described later in this section, but they take on any associated ethical or legal risks.

The history of this technique is as follows. Several years

ago a colleague unfortunately had a patient with refractory leukemia that would not respond as well as chronic thrombocytopenia. He even had antibodies to platelets so that any platelets that were administered were consumed quickly. After he refused thoracic surgery for chest drainage, he was sent to us for a possible procedure. At the time I reasoned that one might be able to use platelets with local administration as an alternate method. Because there was no other alternative, we tried the method and it worked. Since then we have used local injection of platelets and fresh frozen plasma in patients who have an abnormal prothrombin time or low platelet count to partially solve the problem.

If attempts at correcting the problem by systemic administration fail, we use the technique as follows. After preparation of the site with Betadine and local anesthetic, approximately 5 to 10 mL of blood product is injected into the expected trajectory of the needle through the skin, the subcutaneous tissue, and the surface of the organ and target (Fig. 61-16). The procedure is then performed in the routine fashion.

We have reserved this method for aspiration procedures at this time, believing that other steps should be taken if a cutting needle is used. In such cases, one should use a method that includes a guidance cannula and some plugging material such as Gelfoam or angiographic coils (see later).

The rationale for this technique is as follows. First, experience has shown that local infiltration of blood products does not create any problem except local swelling. Everyone of course reflects on previous patients they have observed who have had local infiltration of blood products. No problems occur from the agents themselves. Second, we believe the local injection creates a local "seroma" of the missing product so that if any adjacent vessel is inadvertently punctured, the local elevated concentrate of the blood product provides material for an effective blood clot. With fresh frozen plasma, the seroma concept is appropriate. With platelets, the platelets probably undergo

immediate activation, which provides overabundant amounts of thromboplastin to initiate the thrombosis cascade. A clot formed after the restoration of local or systemic coagulation factors is of better quality than one formed when an imbalance of coagulation factors exists. When a "balanced" clot occurs, this is more effective because studies have shown that the strength of a clot is half due to the platelet agglutination and half to the serum proteins.

Occlusive Hemostatic Methods for Cutting Needles

If there is a severe coagulopathy that cannot be corrected completely, there are hemostatic methods that can be employed to prevent bleeding after a biopsy. The first can be used only when a diffuse liver biopsy is being performed and is not suitable for a guided procedure. The second coaxial method can be used with either a guided procedure of a mass or a diffuse sample of the liver (Figs. 61-17 to 61-19).

Years ago, authors reported the use of a long transvenous (usually jugular access) needle to biopsy the liver through the hepatic venous system. The rationale used is that if one performs a biopsy of the liver from a vessel within the liver, any bleeding would simply occur back into the liver system and not the peritoneum. The risk of such procedures is somewhat less except when the liver is quite small and there is a risk of perforating the liver capsule into the peritoneum. The first versions of this approach were large-bevel, Chiba types of needles that did not work well because only minimal diagnostic tissue was recovered. In years, a side-cutting needle similar to the Tru-Cut design was introduced, which has proven very effective. The other practice that has enhanced this approach is the common usage of a transhepatic decompression procedure for relief of portal hypertension. With a

Figure 61-16. A, CT scan of a former friend (an interventional radiologist) showing a large hematoma in the right chest. Because the patient had refractory leukemia and antibodies to platelets, the platelet level could never be elevated above a total value of 0 to 5. Other clinical services refused to attempt drainage to permit expansion of the lung. A small needle is used along the pathway to infiltrate platelets. (This is not an FDA-approved technique, but it is legal under FDA guidelines.) B, Subsequent scan shows placement of a large catheter in the hemothorax, which was successful and allowed drainage without problems.

Figure 61-17. Schematic picture shows use of a cannula with a biopsy needle to prevent bleeding in a high-risk patient. In A, a plastic cannula is placed over a biopsy needle and a sample is obtained. As noted in B, the biopsy needle is removed but the cannula is left as a conduit to deliver a hemostatic coil. Contrast material may be used as in C to demonstrate the vascular system. Finally, as can be seen in D and E, the conduit is used to deliver hemostatic coils into the biopsy site.

Figure 61-18. A, Radiograph shows fluoroscopically guided placement of coil. The guidance cannula (*long arrow*) is noted proximally, and the “gap” (*small arrows*) of the cutting needle is noted distal to the cannula. B, Follow-up image shows the cannula containing an angiographic wire, after pushing the two steel coils into the liver (*curved arrows*). C, Follow-up CT scan shows the coil in the liver.

Figure 61-19. Schematic diagram showing a similar technique with Gelfoam. In A through D, the biopsy needle is introduced with a plastic cannula around it. As noted in E, the biopsy needle is removed and the cannula left in place. As seen in F, the cannula is used to introduce Gelfoam material to provide hemostasis.

common familiarity of the transjugular pathway, such procedures are commonplace.

The second method is a coaxial one in which the procedure is performed percutaneously. With this method, a coaxial system is used to introduce a needle into the liver. The biopsy is performed through the cannula and the tissue sample is removed with the cannula left in place. Through the cannula, occlusive material is placed into the biopsy site to provide local thrombosis and occlusion. The occlusive material typically used is Gelfoam or angiographic coil, which may or may not be soaked in thrombin before insertion (Figs. 61-17 and 61-18). It is pushed through the cannula with an angiographic wire using the standard Seldinger technique. After the procedure, the patients should lie quietly for 30 minutes to let a clot secure the occlusive material in place. If patients get up too quickly, the device may dislodge into the peritoneum if they happen

to cough or exert themselves; there is no direct harm to the peritoneum except for possible bleeding from the site. This may be used in the liver or other sites as needed.

This method is a rather complicated and difficult procedure unless one is experienced with angiographic methods. With current trends in imaging with vascular surgeons and cardiologists making inroads into taking over angiography, we must continue our development of a nonangiographic method. Even in the best of hands, this older method is fraught with difficulty because of the numerous steps.

In most cases it is better to perform such procedures under fluoroscopic guidance so that the insertion of the coil and material can be followed in real time (Figs. 61-17 to 61-19). With experience such procedures can be performed at the bedside with CT or ultrasound, but this requires extensive experience because with this approach the procedure is essentially "blind" (Fig. 61-20).

Although theoretically this procedure is quite simple, it can be difficult to have consistent results because of the many steps involved. If the patient is uncooperative or moves inadvertently, the occlusive material can be accidentally misplaced. Even under the best of circumstances, the material may dislodge itself. Because of these difficulties we are developing a more simplified introduction device for quickly and accurately introducing the occlusive material.

Patient Positioning

Patient positioning is important for three reasons: patient comfort, anatomic approach for trajectory planning, and producing immobility of a mass in cases where the target may be partially mobile.

Realizing that movement of the patient during a procedure can be troublesome, one should ensure that a patient is on the table in a stable position that is comfortable. If a patient is uncomfortable, it may result in a movement at a most inopportune time or increase the patients' anxiety and their ability to cooperate. This generally affects the patients' ability to control their respirations and so forth.

The other important aspect of patient positioning is that by having the patient lie in different positions, the anatomic access may be easier if internal shift of anatomy occurs. This is true in the abdomen and the chest as follows. On some occasions, it may not be possible to biopsy a mediastinal mass when the patient is in the supine position, but by positioning the patient on the side, access through the anterior junction line may be possible (see earlier section on versatility, Fig. 61-9).

As noted earlier, if a lesion being sampled appears to be quite mobile due to respiratory variation, placing the ipsilateral side down can be helpful to limit the motion of the mass. In such cases, the weight of the viscera partially immobilizes the ipsilateral diaphragm and thereby limits the motion during quiet respiration (see Fig. 61-22).

If a patient is somewhat uncooperative or if the lesion being sampled is small, place the patient in the ipsilateral decubitus or oblique position (not at the compromise of the entrance site, of course). The weight of the abdominal viscera partially immobilizes the diaphragm and limits the respiratory motion of the diaphragm (see Fig. 61-22). This is especially important for lung, kidney, adrenal, or liver lesions.

Figure 61-20. A, CT scan shows a mass in the lateral portion of the right lobe of the liver. B, Cannula with cutting needle is located in the liver; arrow points to gap. C, Scan shows the coil at the end of the cannula being inserted into the liver.

Entrance Site and Trajectory

Site and trajectory planning should be made after a review of the diagnostic scans. The entire procedure can be greatly expedited if one notes the location of the mass, plans the anatomic approach of the trajectory, and decides on the type of needle to be used before putting the patient on the table. In my opinion, a great amount of time is wasted because physicians do not plan ahead for each case but “make it up” as they go.

After the previous diagnostic scan has been reviewed and an appropriate slice has been selected, localization to that slice can be made from the longitudinal type of scan (e.g., Scoutview, Topogram, Synerview). These scans are referenced to the axial slices, making relocation after quite easy. (Some groups have advocated the use of cath-

ter mats or commercial products to aid localization and have found them useful.)

Several general comments about site selection and pathway are appropriate. It is important to decide on a pathway that traverses the least amount of uninvolved tissue and that is also the least precarious relative to possible complications. The concept of using a shortest line to the trajectory is valid; the less liver, lung, or other noninvolved organ crossed, the less the possibility for a problem.

We prefer to avoid pathways that include major nerves or muscles. Involving such structures is painful when traversed and makes it difficult for a patient to cooperate. Common sense dictates that potential problem areas such as arteries and veins should be avoided. Muscles can be a nuisance, because they are highly vascular and can bleed locally. Also, when penetrated, the muscles can be tightened purposely or unintentionally by the patient and cause difficulty with needle placement. The trajectory of a needle can be changed by a muscle contraction. If a powerful muscle group such as the erector spinal or gluteal muscles contracts, a needle can be physically bent (Fig. 61-21). The most notable areas where this can be a problem are pathways through the sciatic notch and the retroperitoneum.

If an oblique or angled approach is to be used, it may be helpful to place the patient in a lateral or oblique position. However, do not put the patient in an awkward position that cannot be held for a prolonged period.

In choosing the trajectory, one must decide whether to perform the procedure within the axis of the slice or outside the axis as an angled approach. If one is a neophyte, it is best to develop experience by choosing the entrance site in the same axial slices as the abnormality.

Skin Preparation

Once the entrance site has been chosen, the skin is prepared with Betadine and a local anesthetic agent such as lidocaine is administered. At the time of lidocaine administration, it is important to palpate the tissue carefully to ascertain the location of the ribs, cartilages, processes, and so forth, so that they can be avoided. This is true especially next to ribs, the sacrum, the scapula, or other bony structures that have a tapered edge or traverse the scan obliquely. Such structures produce a partial volume error in the CT scan that results in a discrepancy between their apparent location on the scan and their actual anatomic location.

When infiltrating local anesthetic, completely infiltrate the pathway in two steps. In the first step, infiltrate the skin, the subcutaneous tissue, and the superficial muscles. After that point is reached, have the patient suspend respiration and then infiltrate the local anesthetic down to and including the pleura, peritoneum, or the capsule of the organ (e.g., kidney or liver) (Fig. 61-22). Such infiltrations should be made as the patient suspends respiration. If the capsule is not adequately anesthetized, the patient may “jerk” the diaphragm during the procedure. It is my opinion that inadequate administration of local anesthesia is the most common cause of poor patient cooperation. If a needle is inserted without anesthesia of the capsule, a “spinal level reflex” occurs; this moves the organ and produces a potential lacerating effect. Adequate anesthesia is also most

Figure 61-21. Picture of a needle (arrow) that was bent by the erector spinae muscle in an uncooperative patient. Compare to the normal needle.

important with anxious patients because they will not cooperate well if they feel pain.

Another important method I have learned and instituted over the past 5 or 6 years has been two new aspects of administering local anesthetic (lidocaine) as follows. The first important point relates to changing the chemical nature of the lidocaine before administering it to the patient, as noted later. The second is the simple methodology for instilling the lidocaine into the injection site itself.

First, it should be recognized that the discomfort associated with the administration of lidocaine is due to the "burning" produced by the acid nature of the lidocaine preservative. One can mix a small amount of sodium bicarbonate into the lidocaine vial that will reverse the acidity. Each day, a nurse should premix the lidocaine vial to be used with 5 mL of sodium bicarbonate into a 50-mL vial of lidocaine. This will neutralize the acid character. This premixed lidocaine can be used only during the day of the mixing and should be discarded the following day.

Painless Local Anesthesia

The second important point is the method of injecting the lidocaine into the projected needle pathway. The traditional method of injecting local anesthetic that we have been taught in medical school is actually an antiquated method based on old approaches and antiquated local anesthetic agents.

The traditional method, which I now believe is obsolete,

was based on the use of procainamide, which was a useful local anesthetic and an effective cardiac antiarrhythmic. The traditional teaching is that one should make multiple insertions and injections in the following fashion. One inserts the needle a small distance, pulls back on the syringe plunger to see if blood is aspirated, and then injects the anesthetic. This process is repeated numerous times until the entire pathway is infiltrated with medication. I believe this is similar to the old torture method of the Middle Ages called "death by a thousand cuts."

My method of administration is as follows. Once the first skin wheal is raised with local injection of lidocaine, I gradually infiltrate the site in the following fashion. I start continuously infiltrating the lidocaine at a very low rate as I slowly move the needle into and through the pathway. In effect, a small boundary of anesthesia precedes the tip of the needle as I infiltrate the path with the needle. The same amount of lidocaine is used during injection during the entire path. Although this requires some practice, the results are spectacular: patients literally feel nothing.

To understand the safety of my method of administration, one must recall how commonly lidocaine is used as an antiarrhythmic agent and how large doses of many milligrams are given intravenously. The probability of having the small-caliber needle cannulate a vessel is astronomically small, and even if a small vessel were penetrated, the potential effects of injecting a small volume of lidocaine are virtually nonexistent. In the past 6 years, I have personally injected hundreds if not thousands of patients. I

Figure 61-22. Small lesions may be difficult if the patient has any variation in respiration. These three images show the methodology for immobilizing the lesion and a method of providing a pain-free procedure for the patient. *A*, This scan shows the patient in a decubitus position with the lesion side down. In such cases one must be sure access is possible anteriorly or posteriorly. On this scan the needle is on the margin of the rib, where lidocaine is infiltrated. *B*, This scan shows infiltration with a small amount of lidocaine in the pleura (arrow), not the raised pleura from the injection. *C*, This scan documents the placement of the needle in the margin of the lesion.

would hope to someday perform a sophisticated study looking at the systemic concentrations of the lidocaine, but the chances of this getting funded are minuscule.

Needle Selection

General selection of the needle should be made before any preparation of the skin and site. Based on the history, appearance of the mass, and the trajectory, one can select the appropriate needle, either aspiration of cytology or cutting needle for tissue sampling.

Since the last edition of this text, there has been widespread acceptance of the principles previously defined. More complete discussion follows in a later section preceding the specific sections on the different organs.

In general if the patient has a known malignancy and the purpose of the procedure is to simply confirm the presence of recurrence or metastasis, then an aspiration needle is the only type required. If the patient presents with unknown disease, possible change of cell type, previously failed aspiration, or suspected benign disease, then a cutting-needle biopsy should be performed. If one looks at a recent survey of patients undergoing liver biopsy, it is quite clear that automated side-cutting needles have become the norm, as we have previously suggested.

A clinical decision about the biopsy must first be made according to the type of information sought by the attending physician from the pathologic sample. Generally, if a patient has a known malignancy and only a confirmation of metastases or recurrence is desired, an aspiration biopsy with a skinny needle is all that is required. If a patient has an unknown problem or if a question of a second malignancy exists, a large cutting-needle biopsy is indicated (assuming laboratory, clinical, or anatomic information does not preclude a safe procedure). Only a sample with such a needle can accurately establish the diagnosis of a lymphoma, benign tumor, or an unusual tumor.

If a clinical decision is made to use a large needle, consideration of clinical, laboratory, anatomic, and dynamic scan information should be made. Clinically, there must be no history of a coagulopathy and the patient must not be on any type of medication that would impair coagulation or platelet function (see section on patient preparation).

Careful consideration of the anatomy, from a recent or current baseline CT obtained during the planning of the procedure, is appropriate. A large needle can be used if clear access is available to the organ of the abnormality (i.e., no intervening uninvolved structure or close proximity of the aorta, vena cava, portal vein, or bowel). As experience is gained, skill increases and one's safety tolerance relative to anatomy improves. For example, although a novice might be fearful of performing a biopsy of a node several centimeters from the aorta, an experienced person will be quite comfortable biopsying some lesions that abut the aorta.

Comparison of Aspiration and Cutting Needles

From a historical perspective, it is important to briefly review previous information about the prior controversy.

Before experience with appropriate cutting needles became common, there were some individuals who advocated the use of aspiration needles (cytologic samples) over those of cutting needles. This was based on a reputed accuracy of diagnostic outcome and increased safety. The fallacy of this position was shown by older literature by Lundquist^{255,256} and Ha.¹³⁶ These articles clearly show the superiority of cutting needles over the aspiration needles.

Domestic and international authors have reconfirmed in recent reports the advantage of diagnostic accuracy with little difference in complications.^{23,217,223,412} Suffice it to say there is no longer a controversy, and virtually all workers concur that cutting needles are superior to aspiration needles. The choice between the two types of needles is dependent only on anatomic factors, slight differences in accuracy and complications, vascular characteristics, and coagulation status. The relative differences in tissue recovery can be appreciated by looking at the material recovered by different types and sizes of needles (Fig. 61–23).

Selection of Aspiration Needle for Cytology

The selection of aspiration needles is quite simple because there is clear laboratory and clinical information that indicates the best types of aspiration needles to use. These points were clearly demonstrated by historical articles and have been reconfirmed over the years without controversy. In the earliest laboratory study by Andriole et al,¹⁰ our group showed that the best sample with the least amount of artifact was the small-angle bevel needle tip and the largest caliber needle (Table 61–1). This was later confirmed by Dahnert et al.⁶⁸

In the direct clinical comparisons, these results were reconfirmed. Pagani et al³¹⁶ showed with aspiration biopsies of adrenal glands that an 18-gauge aspiration needle was better than a 22-gauge. In the lung, there has been no definite benefit shown with large aspiration needles, but there was a larger incidence of hemoptysis shown by Khouri et al.²¹⁴ In the pancreas, Dickey et al⁷³ of our group showed the diagnostic return for a 20-gauge needle compared to a 22-gauge needle, with no difference in complication. Most recently reporting on the prostate, Norbert et al³⁰² showed increased diagnostic yield of the 0.9-mm needle (20 gauge) over the 0.8- (22 gauge) or 0.7-mm aspiration needles.

With our prior experience and the numerous reports as noted earlier, we have consolidated the needle choices in our institution to use the 20-gauge Chiba needle in all organs. It is suitable for all organs and has an acceptable complication rate relative to all organs sampled.

Selection of Cutting Needle

Before one selects a cutting needle, a number of factors need to be considered, including the site, trajectory, and local anatomy (see earlier sections on site preparation). The other critical factor to evaluate is the local vascularity of the tumor lesion. The reason there is little information about the different calibers of needles is the fact that needle caliber is a minor determinant of bleeding. The numerous

Figure 61-23. The type and relative size of specimens obtained with four different needles. Specimen **A** was obtained with three passes of the 22-gauge skinny-core needle using 30 mL of suction and a 2-cm insertion of the needle. Specimen **B** was obtained in one pass of an 18-gauge bevel-end needle using 30-mL of suction and a 2-cm insertion of the needle. Specimen **C** was obtained with an 18-gauge Menghini needle using 30 mL of suction and a 2-cm insertion of the needle. Specimen **D** was obtained with the Tru-Cut needle and no suction.

Table 61-1. Comprehensive Quantitative Comparison*

Needles	Type of Needle	Average Weight of Sample (mg)
22-gauge	Chiba	4.1 ± 0.1 SD
	30-degree bevel	4.0 ± 0.1 SD

† Modified Menghini needle.

technical factors and anatomic factors discussed are important, but the other important factors are the approach (discussed in the various sections on the body organs) and the vascularity of the lesion.

The first point that should be clarified is the predominance of the biopsy gun over manual needles. When we first introduced the concept of using the side-cutting needles, one manual Tru-Cut needle was available. Radiologists were not comfortable using the manual device. Other vendors were able to manufacture the device because of patent restrictions. Once the original patents expired on the cutting tips, automated guns were introduced and radiologists overwhelmingly accepted the concept of cutting needles. A recent survey by Mayoral and Lewis showed over 90% of radiologists doing liver biopsies use these devices; the only variabilities are the vendor and caliber of the needle.²⁶⁶

In every case when a tumor is to be biopsied, one must have an imaging procedure that demonstrates the blood flow. This can be done by a basic visual technique or a more sophisticated computer program now available on many scanning devices. The importance of the basic vascularity on the incidence of biopsy can be appreciated by noting the incidence of complications in the liver when bolus scans are used to biopsy the liver and those series of cases where no such assessment occurs. Bret et al³⁷ reported a series of biopsies on hepatoma patients using 22-gauge aspiration needles and had a hemorrhagic complication rate of almost 5%. In our 12-year experience of liver biopsies using 14-gauge needles, we reported a hemorrhagic complication rate of 0.5% in a group of 200 patients (see liver section).

In general one must decide which caliber of cutting needle is optimal for achieving the appropriate diagnostic sample with the acceptable amount of risk of complication. There is some information in the clinical literature that will

indicate what the proper choice of needle caliber is for specific patients, but there has been some laboratory work performed by our group that sheds considerable light on the tradeoff between needle sizes as they affect recoverable sample and bleeding. In a paper by Plecha et al,^{328a} our group studied the outcome in an animal model using 20-gauge, 18-gauge, and 14-gauge needles. In the study, the authors evaluated the amount of diagnostic information compared to the amount of bleeding by weighing the amount of DNA (nuclear material) and blood in the tissue sample. They noted that the larger the amount of tissue required for the diagnostic information, the more efficient it was to use a large-caliber needle.

A number of clinical articles have studied the histologic information obtained from tissue samples for kidney and other organs. Hopper et al¹⁸¹ showed that sufficient diagnostic tissue could be obtained from the kidney with an 18-gauge needle in the pediatric age group. Haage et al¹⁶⁰ found in a comparison of 18-gauge and 14-gauge needles that the diagnosis was equivalent for both devices. A recent survey among gastroenterologists and radiologists showed that most physicians use an automated side-cutting needle in the range of 18-gauge.²⁶⁶

While the use of the 18-gauge needle is the norm in the United States, there is good reason for radiologists to begin using even large-caliber needles within the general body area. In recent years, new methodologies have been developed at our institution in conjunction with the National Cancer Institute that portend to enhance the development of new cancer agents and drugs by using samples from 14-gauge needles.^{75,125a} The traditional method for drug development over the years has been to locate patient tumors by imaging and enter them into a protocol of periodic diagnostic examinations. The drug trials would indirectly monitor the effects of the drugs on the tumors by watching the change or lack thereof based on the imaging appearance. The trials would run for long periods with little accurate information about the real effect of the drug on the target site of the end organ. By the use of the large needles and microchemistry techniques, the histologic samples recovered are used to assay the specific target site of the cytolytic or modulatory agent. It is believed that adoption of our methods by other cancer centers would bring about more rapid drug development at a lower cost. From the work of our institution, the agency has actually coined a new phrase for the goal of pharmacokinetics and dosage determination of drugs. Instead of trying to find the MTD (maximum tolerable dose, i.e., maximum dose used before unacceptable complications occur), the goal of the new program is to find the BMD (biochemical modulatory dose, based on end target site in the tissues from tumors).³⁶⁸

Needle Choices in Coagulopathic Patients

There is little indication in the literature that needle caliber has any significant impact on bleeding if the patient has normal coagulation and the proper careful technique has been used. In our experience with normal patients recently reported by Dowaloti et al,⁷⁵ we had a 0.5%

Table 61–2. Separation of Means of Biopsy Blood Loss Data by Needle Gauges

Target Organ	Groupings of Needle Gauges	P Value
Liver		
No warfarin	(14) (16) (18, 20, 22)	<0.01
Warfarin	(14) (16) (18, 20, 22)	<0.01
Kidney		
No warfarin	(18, 20, 22)	NS
Warfarin	(18, 20) (22)	<0.05

Note: Groupings within a single set of parentheses taken are equal, versus those grouped those in other parentheses.

NS = not significant.

bleeding rate with 14-gauge cutting needles in the liver, in a series of 200 patients.

In coagulopathic patients, one assumes there must be a difference in the bleeding rate with different caliber of needles, but it would be difficult to design a clinical study from an ethical perspective that would shed light on this question. In a previous laboratory model from our institution, Gazelle et al¹⁰² from our group reported on the effect of anticoagulation on blood loss in two organs: the liver and the kidney. Using aspiration needles, they found that there were absolute differences in local bleeding with various calibers of needles, as shown in Tables 61–2 and 61–3. We also showed that by using a occlusive hemostatic device, the amount of bleeding was acceptably limited.¹⁰² From these data, we believe that the development of a simple, effective hemostatic method will encourage more widespread use of larger cutting needles.

Needle Techniques

Since the prior edition, the needle techniques have matured so the only two general approaches now used are the single-needle or coaxial-needle method.

The *single-needle technique* is simple because it uses the primary instrument as the device primarily localized. This is typically used when one anticipates taking only a single sample. The most usual clinical scenarios differ with the aspiration needle and the cutting needle. With a Chiba

Table 61–3. Summary Statistics Based on Raw Data

Needle Configuration	Drug Treatment	No. of Procedures	Mean Blood Loss (g) \pm SD
Tru-Cut only	None	32	2.46 \pm 1.37
	Venopirin	30	4.60 \pm 1.71
PPS	None	21	0.31 \pm 0.15
	Venopirin	27	0.61 \pm 0.28
Thrombin-coated PPS	None	14	0.11 \pm 0.06
	Venopirin	24	0.23 \pm 0.14

Note: The statistics are based on raw data for blood loss caused by liver biopsy performed with differently configured biopsy needles in pigs, with or without venopirin treatment.

needle and a lesion that is fairly large and accessible, it is easy to perform several procedures as needed without concern about repeat positioning of the needle. With large cutting needles, it is usually when a 14-gauge needle is used to obtain a sample; seldom are multiple samples needed in such a circumstance.

Coaxial methods are now commonly used and offer significant advantages. In the prior edition we made a distinction between a short cannula and a long cannula. Essentially that terminology is irrelevant because vendors now market coaxial systems, with a cannula that is medium length. This permits one to use it superficially or as a deep cannula. In the superficial mode, it permits repetitive sampling of moderate or small lesions without repeat localization. In the deep mode, it can be helpful for minimizing several possible adverse outcomes from procedures.

Using a deep cannula, one can ensure precise placement of a sampling needle into a small site with the flexibility of taking multiple samples or changing instruments without repetitive positioning efforts. The second benefit of the cannula is that it prevents seeding of either infectious material or tumor cells along the pathway, which can have adverse effects. As noted later in the liver section, with the increased interventional activity, more cases of needle tract seeding have occurred. The use of a cannula potentially permits a multitude of procedures with the access provided. Multiple procedures with different needles or instruments are possible. Finally, the cannula can also be used as a conduit for the deposition of occlusive material as needed should some type of bleeding occur, as discussed earlier in the section on hemostatic methods.

The only place where the use of the coaxial cannula is of some question is in the lung. One must be careful when dealing with the lung to not puncture the pleura and cause a pneumothorax. I personally do not use the coaxial system in the lung for this reason. In the mediastinum its use is quite helpful (see later).

Basic Sampling Method for Aspiration and Cutting Biopsy

Aspiration Technique

The standard aspiration procedure is quite simple but can be broken down into three individual steps as follows: (1) application of suction, (2) movement of the needle, and (3) delivery of the sample to the appropriate medium for evaluation (Fig. 61–24).

As noted earlier, the best device to use for aspiration sample is the 20-gauge Chiba needle, which can be used in virtually every organ. Once the tip of the needle is correctly positioned in the area of the lesion, the following steps are taken. Some type of device for achieving vacuum is applied to the hub of the needle.

The best technique is to use a one-person approach to apply suction to the hub using a syringe. The amount of suction to apply has been evaluated by our group and others.^{84,184,222} Both our group and Kreula²²² had similar findings. In a laboratory model, we found that displacing the syringe barrel by 5 mL produced about 84% of obtainable sample and that displacement of the barrel by 10 mL produced 94% of the obtainable sample (see Fig. 61–24).

There was an “apparent” slight discrepancy between Kreula’s data²²² and ours, but there is a simple explanation. Kreula found a straight-line relationship between the sample and the vacuum, but the fact is they only measured the effects between 0 and 5 mL of displacement.

Several other points merit discussion. To maximize the vacuum during the movement of the barrel, it is important to make sure all of the air has been expressed from the syringe before hooking it up to the hub. Even a small amount of air dilutes the vacuum when the barrel is moved.

During the removal of the needle, it is important to maintain the suction to retain any fragments in the lumen of the cannula. The *in vitro* study our group performed documented the small but definite benefit of this process (Fig. 61–25).

Historically, some groups advocated the use of no suction during the sample acquisition. This “capillary” method works with very necrotic tissue like squamous cell tumor but not with most tumors. Some authors have asserted that the application of suction pulls too much extraneous material, especially blood, into the needle, but a recent study by Ha et al¹³⁶ showed that such degradation only occurred in 6% of cases; this slight tradeoff is minimal compared to the improvement of the sample. Furthermore, depending on the fixative chosen, the red blood cells can be lysed by certain additives to the fixative material and thereby eliminate the problem.

Number of Needle Passes

With appropriately planned procedures, one can minimize the number of needle passes and thereby save time and reduce the risk to the patient. It is quite clear from our experience⁷³ that equivalent diagnostic accuracy can be obtained from two well-positioned, meticulously performed aspirations. Our results compared favorably with other authors who recommended four or five needle passes.

The incidence of complications increases accordingly with the number of needle passes. Numerous reporting authors^{89,219–221} support the association of passes with complication frequency. One important article by Smith³⁵⁸ who described sampling the pancreas with four or five passes, stated that there was a direct relationship between passes and complications.

The emphasis on taking many needle passes has evolved incorrectly from misinterpretation of an article by Ferucci et al^{87,89} (Table 61–4). These authors took a sample of 20 cases, proven positive by cytologic results, and looked at the incidence of positivity with each needle pass. At first glance one would believe 100% accuracy could be achieved with many needle passes, but this is not true. Of course 100% of this group had positive results because they were selected as positive at the onset. In the same study the unselected group had only an 82% accuracy despite their protocol of five passes on every patient.

Sample Preparation

After a sample has been taken, it is critical that it is properly handled. Perform the smear quickly in close proximity to the fixative to prevent drying, which can occur quite quickly. Always flush the syringe and needle with fixative and send the fluid for tissue cell block or cytocen-

Figure 61-24. The five steps in obtaining an aspiration specimen. *A*, Insert the needle adjacent to the lesion, represented by the "core." *B*, Retract the stylet several centimeters and make several in-and-out motions and rotations of the needle to "free" up some cells. (*figure continues*)

Figure 61-25. A, Sample size versus suction, 18-gauge needle. Each point equals average of five samples. B, Sample size versus suction, 20-gauge needle. Each point equals average of five samples. C, Theoretical pressure change as calculated by Poiseuille's law for noncompressible fluids ($Q = \frac{\pi r^4 \Delta P}{8 \eta l}$). Q = volume of fluid through cylinder, P = pressure difference at ends of cylinder, r = radius of cylinder, l = length, η = viscosity of fluid) and Boyle's law for ideal gases ($PV = PV$ at constant temperature, P = initial pressure, V = initial volume, P = final pressure, V = final volume). D, Specimens 1 to 4, average of 5 human samples, specimen 5, average of 10 bovine samples; c = with s = without. (D, From Hueftle MG, Haaga JR: Effect of suction on biopsy sample size, AJR 147:1014-1016, 1986.)

trifuge, whatever the routine approach is at your institution. This can increase the diagnostic yield by several percentage points. One author²⁰⁷ has reported that heparinizing the needle and syringe is helpful, but no other workers have confirmed this. Others have measured the carcinoembryonic antigen in the cytologic samples and found this test useful.²³¹

Side-Cutting Needles

The type of cutting needle used throughout the world is based on the original side action cutting Tru-Cut design. This manual device demonstrated in Figures 61-26 and 61-27 is the prototype of virtually all cutting needles used today. The percentage of end-cutting needles originally

represented by the Menghini needle is used in only a small percentage of cases. Rather than delete the images used in the prior editions, I have retained them because they show in individual frames the action of this needle that are now used almost solely in an automated spring-loaded variety. By understanding the basic action, one can better appreciate any future permutation of this classic design.

The chief benefits of this needle are several-fold. By numerous in vitro tests by ourselves and Hopper,¹⁸¹ this design provides the most complete and preserved samples of all needle types. Also, because the location of the biopsy is confined to the "gap" of the needle, one can carefully localize the site of the biopsy. The action of the needle is so precisely predicted that it can be used in close proximity to other structures.

Another advantage of this needle is that the tissue gap

can be moved or adjusted as needed without any adverse effects on the tissue. The cutting action takes place only when the outer cannula is advanced forward either manually or by the spring device.

Relative to use of the needle, there are several points that will improve the diagnostic yield and minimize the possibility of complication. To improve the diagnostic yield, two factors should be kept in mind. When spring-driven devices push the stylet forward, there is actually a backward recoil of the device. Because of this motion, the device should be held firmly. In a study by Kellermeyer,²⁰⁹ he found that holding the needle firmly would improve the yield by reducing the recoil. In his unpublished data, there was a 14% improvement of the yield. Another anecdotal factor is that one should hold the device exactly as explained in the instructions. If an operator holds such a device casually without the fingers in the correct location, the movement of the actions may be impeded and the sample less than optimal.

There is one word of caution about these needles, relative to bending. These needles should not be used for very hard tumors or bone. The thick waist of these needles can bend if too much force is applied, even if the needle is closed (Fig. 61-28).

Assessing Vascularity

Before sampling any abnormality with any type of needle, either aspiration or cutting type, one should have an

Figure 61-26. Picture of the four needles used. Insets show the needle tip of each instrument. The 20-gauge Chiba needle (A) is used for aspiration biopsies. The 19-gauge needle with the 18-gauge sheath (B) is used for aspiration of fluid collections. The Menghini-type needle (C) is used for cutting biopsies of "hard" lesions. The 14-gauge Tru-Cut needle (D) is used for biopsy of most tumors.

Figure 61-27. “Core” biopsy of an apple using the Tru-Cut needle. *A*, Insert the needle in the closed position to the margin of the lesion. *B*, Insert the inner stylet with the “gap” (arrows) briskly through the area of the lesion. (If the needle is improperly positioned, it can be withdrawn in this position; a specimen will not be cut unless the outer needle is advanced over the gap.) (*figure continues*)

assessment of the vascularity. From my experience and review of the literature, the nature of the abnormality is a major determinant of bleeding complication. One can note that high bleeding rates occur even with 22-gauge needles when vascular tumors such as hepatomas are biopsied.⁵¹ On the other extreme, such as in our latest series of 200 liver biopsies in which we use a bolus injection to assess vascularity, the complication rate with a 14-gauge needle is 0.5%.⁷⁵

In most instances, the vascular character of the lesion is apparent from a prior contrast-enhanced study. If not, one

should perform a bolus of contrast material with repetitive scans at the site of the biopsy to evaluate the vascularity.

Needle Positioning

Axial Slice

Positioning a needle in the same xy plane of an abnormality is the simplest approach, if at all possible. In these cases, with the needle in the superficial tissues, the angle of the needle is adjusted with repetitive scans until angled

Figure 61-27. *Continued.* *C*, With the inner stylet (arrow) held stationary, advance the outer needle rapidly over the gap. (The outer needle cuts the specimen into the gap.) *D*, A hard material such as bone (in this case, an apple seed) can deflect the thin portion of the needle. This has never been a problem with soft tissue tumors, but the Tru-Cut needle is not suitable for lesions in or against bone for this reason.

Figure 61-28. *A*, Scan shows a bend in the middle of the gap, while in a patient. The fibrous material was so hard it bent the needle. *B*, Scan shows the bent needle after it was extracted.

correctly. Once the correct angle is achieved, the device is inserted to the desired depth with either incremental adjustments and repeat scans or to a premeasured distance. Subtle adjustments using the deflection principles or cannula manipulations noted in the following sections may have to be employed for small final adjustments close to the mass.

Angled or Out-of-Slice Targeting

When a needle must be inserted into a lesion located at a different *z* axis position, different approaches must be taken. There are three approaches that can be taken: (1) free hand, (2) angle estimated, or (3) device assistance.

Free-Hand Method

With the free-hand approach it is best to consider the approach to the lesion as a three-dimensional system. The final vector or angle of the needle to the lesion will be a combined angle consisting of the *xy* angle and the *yz* angle. When doing this it is best to establish the *xy* angle in the superficial tissues of the lowest slice before attempting the *z* angulation. Once the *xy* angle is proper, one can consciously hold that angle constant while moving the needle into the *z* axis (Fig. 61–29).

When the needle is close to the target site, one makes numerous scans over the path of the needle to judge the position in the three dimensions. If a minor adjustment needs to be made, one should then use the tip deflection method described later. Using this technique after the first major angulation has been accomplished saves time and makes success more likely.

Angle-Estimate Method

The angle-estimate method is really just a permutation of the free-hand method, but more care is given to trying to calculate or simulate the angle more precisely. Most simply this is done by using a calculation of the Pythagorean angle from the scans to arrive at a numerical angle in the different planes (Fig. 61–30). The execution of the instrument insertion is performed by the free-hand method or by using a manual angulation device.

Assisted Devices

There are now available two assisted devices for guiding biopsy procedures: articulated arm device and localization device by electronic means. The articulated arm device (marketed by Phillips) consists of a software package integrated with the image files on the computer. The position and angulation of the device are calibrated so that a “virtual” needle presents itself on the monitor to serve as a guide for the needle. The articulate arm is quite accurate and duplicates the pathway of the virtual needle that has been chosen by the operator.

The other device used for CT localization consists of sound- or light-emitting holding devices that secure the needle. A receiver coupled with a computer localizes the needle in the three-dimensional space and displays it on the monitor. This has proven effective and has gained significant popularity in the marketplace. Rather than discuss such products, the reader is referred to the commercial realm for evaluation of available products.

Figure 61–29. A, An entrance site below the mass is chosen so that the needle is introduced below the diaphragmatic insertions. The *XY* angle is approximated and needle inserted partially. B, Higher scan at the level of the cyst (*curved arrow*) shows that the trajectory of the needle (*arrow*) is slightly too medial for puncture. The needle was withdrawn slightly and the bevel rotated, as demonstrated in later scans, so that the point is directed laterally and the needle is pushed slowly to facilitate the subtle bending. C, Final scan shows the needle centrally in the cyst. Fluid confirmed the simple nature.

Robotics

Everyone is aware of the classic childhood story of “Paul Bunyon and the Steam Machine,” where the machine provides more rapid “logging” than even the great lumberjack legend. With the resolution and computers in recent years, there is no question that in the near future robot-assisted procedures will become available.

To be realistic, there will always be the need for the caring physician/radiologist to be on site to use the robotic

Figure 61-30. Calculation of the distance to the lesion and angle of entry when the entrance point to the skin and the target lesion is not in the same CT section. When the entrance point C and distances A and B are known, the distance to the lesion and the angle of insertion can be calculated. Although theoretically this method has merit, pragmatically its use is limited because of the difficulty in duplicating the angle "freehand." We prefer to estimate the angle with such lesions and take a series of sequential scans or use the longitudinal scan method.

Figure 61-31. A, B, Pin point product has an articulated arm that provides coordinate information on image screen. The localization device provides accurate measurement and guidance for placement of the needle at the surface of a patient.

Figure 61-32. Diagram in A shows a schematic where the needle is not accurately positioned adjacent to the mass. Diagram B, shows how the needle can be redirected toward the mass by pulling the skin away from the point and pushing the needle slowly.

assurances, monitor the procedure, and manage the patient, but targeting lesions will be much easier. We have performed some initial testing using a standard industrial robot and have found it to be quite interesting (Fig. 61–31).

In a swine model, we tested a robot for the execution of a celiac nerve block. Much to my surprise, the execution of the procedure was faster and more precise than I ever imagined. Unlike manually performed procedures during which needle adjustments are made below the skin surface to account for small errors during the insertion, the robot executed the insertion quickly without error.

The final configuration and type of robot have yet to be determined, but I expect to personally continue research on robots in the future.

Needle Deflection

With a bevel needle, the needle will move either straight or deflect depending on the hardness of the mass, the angle of the needle, and the speed of insertion. If a needle is pushed quickly, it tends to go straighter. If it is pushed slowly, it is more likely to move toward the point away from the flatter part of the needle. Depending on the consistency of the target, the movement may or may not be enhanced. In very soft materials or fluids, no deflection can occur. In moderate-density material, controlled deflection is possible. This typically corresponds to the texture of normal solid organs. Pathology tends to be harder. With hard material, deflection is the rule, not the exception.

Intentional Deflection

A useful technique that can be of benefit for the final positioning of a needle is the needle deflection technique using bevel needles. Intended deflection can be enhanced to change the angle of the needle at the latest stage of adjustment before striking the mass. This is best accomplished by rotating the needle so the flat side of the bevel is facing the area one wishes to avoid and the point is directed more toward the target direction. The skin adjacent to the needle is pulled away from the point. This changes the fulcrum of the needle so that it is more angled toward the target (Fig. 61–32). The needle is then pushed slowly.

With this method, one can change direction of a needle when it is located in a patient below the surface of the skin. By using the proper method, one can change the direction of the needle by 10 to 15 degrees and prevent the need for a major readjustment or reinsertion of the needle (Fig. 61–33). This technique can be used for needles 18 gauge or less. It can even be used with the stylet of a cutting needle (Fig. 61–34). This will work with needles 18 gauge or less in caliber.

Avoiding Unintended Deflection

Unintended deflection may occur when masses are very hard. The methods to compensate for unintended deflection or intended deflection are as follows. With hard masses, a beveled device, either needle or stylet, is more likely to enter the mass if the needle is pushed quickly. For very hard masses, deflection cannot be avoided unless one continuously rotates the needle during insertion or a stiff

Figure 61–33. These three radiographs (A to C) show the position of a needle tip that is moved by the deflection method (see text). Note in the first radiograph (A) the needle tip is adjacent to the lower end plate of the L4 body. In B, the needle has been retracted back slightly before the deflection maneuver. The skin was retracted and the bevel rotated cephalad as noted above and the needle was pushed forward. In C, one can see that the needle tip (arrow) was deflected caudally almost 10 mm to the top of the L5 end plate.

guidance cannula greater than 18 gauge is used. This is a very rare circumstance, but it can be perplexing when it occurs.

Coaxial Cannula Manipulation

Because the coaxial approach has such benefits as described earlier, one should consider the possibilities with the guidance cannula. Because the guidance cannula is

Figure 61-34. Diagram shows the same result of deflecting the needle tip with a side-cutting needle. By pushing the needle at an angle and then slowly pushing out the stylet, the bevel of the stylet can direct the needle into a mass when there is a slight trajectory error.

stiffer than the basic needle, it can be used to torque the needle. This is done by simply angling the cannula in the desired direction. One must be aware that such devices are stiff, and moving such a device can potentially produce shearing.

It is true that the intended deflection noted earlier will and can occur with a coaxial cannula. Another technique to move a needle into a difficult area can be used that combines the benefits of a Chiba needle with a cannula. For lack of a better term, I have called this a *cannula slide maneuver* (see Fig. 61-90A-C). If one wishes to use a cutting needle beyond a vital structure, one can advance the cannula in the following fashion. Through the cannula one pushes a bevel Chiba needle beyond the vessel. Then one advances the cannula forward over the small-caliber needle. When the cannula is distal to the vital structure, one can safely use the cutting needle.

Rotation of Cutting Needle to Optimize Sampling

In some cases when a biopsy is being attempted with a side-cutting needle, the placement is not completely opti-

Figure 61-35. In some circumstances, the “gap” of a cutting needle is close to the edge and one cannot be completely certain the cutting side will obtain a suitable sample. In such cases, one can optimize this possibility by rotating the needle 180 degrees so that the gap faces the tumor.

Figure 61-36. A, Scan through the liver shows the gap of the needle faintly visible in the lesion. B, By rotating the needle, the gap is turned so the cutting edge is toward the mass. There is a greater probability that an adequate sample will be obtained.

mal because the “needle gap” misses the mass slightly. In such cases, one can increase the probability of getting an adequate sample by rotating the needle so the gap is oriented toward the center of the mass (Figs. 61-35 and 61-36).

Localization of the Needle Tip

After insertion of the needle, one may occasionally have some difficulty in localizing the tip. There are several methods that can be used to solve this problem. The simplest method is to take a longitudinal scan and take an axial slice at the end. This is virtually foolproof and is the most expeditious. Another method that can be used if the angle of the needle is slight involves simply taking multiple scans in one direction until the end of the needle is reached (Fig. 61-37). Some of the new scanners have a cluster scan feature consisting of three or more scans, which is well-suited for this purpose. When the end of the needle is found, it will appear to have a square end and may have an artifact from the end. On occasion the end of the needle will not be “square” in appearance, but the end is easily appreciated by noting when the end is no longer seen on sequential scans.

Respiratory Variation

For the routine circumstances, one can encourage the patient to take consistent breaths by using the following approach. Most patients become confused and frustrated if

Figure 61–37. Localization of the needle tip may be problematic at times. When the needle is “tapered,” as seen in *A*, it means that a variable number of pixels is being occupied along the length of the needle and thus the end may not be seen. When the end is “square,” as in *B*, the tip is being accurately localized.

one tells a patient to “take a deep breath” or to “blow your air out and hold it.” The best approach is to simply remind the patient to take a normal breath and hold it.

When patients are anxious and not cooperative, their respiratory efforts may vary in depth. In such cases the best opportunity to lessen the movement is to use the lateral positioning as described earlier (p. 2144).

Percutaneous Tissue Retraction

When only a skinny needle is used, it is permissible to penetrate certain loops of bowel and organs. If one is using either a cutting needle or catheter or dealing with an immunocompromised patient, one should not penetrate or traverse any intervening structure. Two methods have been used for dealing with this problem: the injection of carbon dioxide and the injection of saline.

We have reported¹⁵⁹ that carbon dioxide insufflation can be used to move bowel and the bladder a short distance; in this fashion a pathway for such a procedure can be opened. However, this gas will not move solid organs such as kidneys.

The procedure is easily performed as follows. After the trajectory is planned, decide from the scans the proper

location of the carbon dioxide. Then insert a needle and inject by hand 50 to 100 cc of carbon dioxide (Fig. 61–38). If the intended loop of structure does not move, attempt to reposition the needle or repeat the injection of carbon dioxide. Although this requires some practice, generally try to get it in a location such that the gas will move the bowel perpendicularly away.

Although there are some theoretical objections, the use of carbon dioxide is quite safe. This gas has been used for all types of in vivo procedures, including peritoneoscopy, mediastinal insufflation, and even intravascular use, without any difficulty. The gas is absorbed very quickly because carbon dioxide is quite soluble in body fat.

Other authors¹³¹ have proposed the use of injected saline to increase the size of pathways through which one can insert a needle. This has been used predominantly in the chest for widening the paraspinal space, but potentially it could be used in other localizations (see later section on biopsy of middle mediastinal tumors) (Fig. 61–39).

Both of these methods have a similar problem. Depending on the location of connective tissue, either the gas or fluid may dissect cephalad or caudad and not substantially produce enlargement in the axial plane. Nevertheless, both of the methods can work in selected cases.

Langen et al²²⁸ studied the efficiency of carbon dioxide

Figure 61–38. *A*, Scan shows a tumor (T) in the right lower quadrant. The needle (arrow) is inserted adjacent to the bowel, to be moved. *B*, Air (10 to 15 cc) is injected quickly to push the bowel away. The gas with the needle is noted adjacent to the bowel (arrow). The metal needle shaft is not well seen because of the partial volume of air with the metal needle. *C*, With the bowel moved away, the needle could be inserted into the mass.

Figure 61-39. A, Scan taken during a biopsy of a middle mediastinal mass in the area of the aorticopulmonary window. The trajectory chosen to reach the mass is through the anterior junction line but is difficult because of the narrow pathway. B, Injection of saline at the site moves the pleura 7 to 8 mm laterally. This widened pathway permits passage of a needle. C, A Chiba aspiration biopsy needle was passed through the parasternal path into the mediastinal mass. The lung parenchyma was totally avoided. D, The same pathway was used for passage of a cutting needle. The needle is seen prior to the insertion of the cutting stylet. E, The stylet is inserted with bevel turned toward the mass, so the stylet deflects laterally away from the margin of the aorta.

and saline in an animal model to move structures from a needle trajectory pathway. With equivalent amounts of gas or saline, they found the saline produced substantially more movement of organs than carbon dioxide. The maximum distance was slightly greater than 1 cm. The caveats for saline injection include patient discomfort, decrease in target-lesion conspicuity, and adverse effects of absorbed fluid in patients with kidney or heart disease.

The optimal methods for carbon dioxide injection have yet to be defined experimentally. One caveat that should be mentioned is the effect of severe inflammation or tumor invasion. If either of these are present around the structure being pushed by the saline or carbon dioxide, the structures will not move effectively.

If a patient is somewhat uncooperative or if the lesion being sampled is small, place the patient in the ipsilateral decubitus or oblique position (not at the compromise of the entrance site, of course). The weight of the abdominal viscera partially immobilizes the diaphragm and limits the respiratory motion of the diaphragm (see Fig. 61-22). This is especially important for lung, kidney, adrenal, or liver lesions.

Lungs and Mediastinum

For the routine well-defined pulmonary nodule, fluoroscopy and CT are now the modalities of choice. Since the first edition of this text,¹⁴⁵ our experience with CT biopsies of the lung has been considerable, and CT has surprisingly developed a much larger role than anticipated.⁵⁵ In fact, almost all lung biopsies are now done under CT guidance. This is true for two reasons. First, there has been such a refinement and development of CT procedures that almost any lung nodule can be biopsied with CT guidance.³²⁹ Second, the availability of sophisticated fluoroscopy equipment is limited because of its use for many current vascular procedures.

If CT expertise and/or the appropriate equipment is not available, one can use either fluoroscopy or ultrasound.¹¹⁶ The primary role of ultrasound is still the aspiration of pleural fluid; its minor role is the sampling of pleural-based nodules.

Indications

The clinical situations that justify the performance of a biopsy include sampling of nodules for neoplasm or sampling of infiltrate for infectious agents. One can justify performing a biopsy of a suspected primary nodule for two reasons. First, aspiration biopsy can distinguish small cell tumors from non-small cell tumors.³⁵⁶ Many oncologists believe that small cell tumors should be treated medically rather than surgically. Second, Sinner et al³⁵⁶ stated that percutaneous biopsy can expedite surgical treatment. Obviously, confirmation of malignancy in cases of metastatic or recurrent tumors is important. In cases of pulmonary infiltrate when the causative organism is unknown diagnostic aspiration can obtain material for culture that can distinguish among pyogenic, fungal, or opportunistic organisms.

CT is indicated for the biopsy of a variety of lesions

Figure 61-40. Sagittal scan close to the central chest shows the relationship of the various ribs. Anteriorly, there is fusion of several costal cartilages (*vertical arrow*). Posteriorly, one can see the ribs are much closer than anteriorly. In addition, the narrowing size of the ribs as they approach the apex shows how the inter-spaces become more narrow owing to the close proximity of the ribs (*curved arrow*).

not well-suited for fluoroscopy or ultrasound because of their locations as well as other factors. Lesions in the apices (Figs. 61-40 to 61-42), the costophrenic angles, the costovertebral angles (Fig. 61-43), the pleura, the hila (Fig. 61-44), and those obscured by fluid and mediastinum are best suited for CT because they are not well seen with fluoroscopic imaging. The dynamic-bolus CT scan is an important adjunct for the mediastinum and hila because major vessels can be opacified and delineated, making separation from masses in these areas quite easy.

Parenchymal lesions well-suited for CT biopsy also include those lesions with ill-defined edges, as well as other lesions poorly visualized by fluoroscopy. These latter lesions are better seen because of the better contrast resolution and the tomographic nature of CT scans.

Figure 61-41. Lesion in anterior apex adjacent to the mediastinum. Needle (*arrow*) can be noted anteriorly entering the mass without traversing any intervening lung. In such cases one must be careful to avoid the subclavian vein, which was at a level slightly higher.

Figure 61-42. Mass in the posterior paraspinal region can be approached without traversing lung parenchyma.

Peripheral nodules in patients with severe parenchymal disease are well-suited to CT. Blebs are also more easily avoided with CT by careful planning of the trajectory (Fig. 61-45). In such cases if one takes thin scan sections, one can sometimes find a pleural attachment that permits a “risk-free” access, thus avoiding penetration of the lung.

Contraindications

With the further refinement of techniques, the number and significance of contraindications have lessened. There are several absolute contraindications that include uncorrectable coagulopathy, severe pulmonary hypertension, uncontrollable coughing, possible *Echinococcus* infection, and an uncooperative patient insufficiently controlled by anesthetics.

Figure 61-43. Biopsy of pleural-based masses can be easily and safely accomplished with cutting needles, if the gap (arrows) of the needle is confined to the mass. Note the thin fat line of retracted pleura adjacent to the mass, indicating adherence.

Figure 61-44. A, When a large mass (M) is adjacent to the hilum, a bolus injection should be performed to localize the pulmonary artery (P). B, This scan shows the needle biopsy of the central mass, at a level above the artery. The distal lung is atelectatic.

The levels of the coagulopathy that I find acceptable are a prothrombin time within normal range, INR of 1.0, and a platelet count of at least 50,000. Virtually normal values are important because the air-filled lung cannot tamponade bleeding, which would result in serious bleeding. Uncon-

Figure 61-45. This scan shows the approach of a mass in the right apex. The needle is positioned to traverse the “fibrous band” (arrow) traversing to the pleura. This approach minimizes the possibility of a pneumothorax.

Figure 61-46. Because a cutting needle was being considered, this bolus injection was performed. Note the remarkable vascularity in the mass, later proved to be an angiosarcoma. If a biopsy had been performed, it surely would have been catastrophic.

trollable coughing and a patient with an uncooperative nature are important because movement of the lung during a procedure may cause a tear of the lung by the needle that might cause air embolism, pneumothorax, or bleeding.

Techniques for Lung Biopsy

There are several important techniques used for chest biopsy that relate to both the preparation of the entry site and the needle technique. Appropriate choice and preparation of the entrance site are important to ensure a painless and successful biopsy procedure.

Although it has not been traditional in the past, I now believe it is important to perform a bolus injection for lung biopsy in a number of circumstances. First, if the patient has any history of bruit on auscultation of the chest, a bolus should probably be performed (Figs. 61-46 and 61-47). The other circumstance would be in those instances when there is no clear history of smoking or other risk factors for a tumor. A bolus is *absolutely indicated* if any consideration of a cutting needle is being made.

After one has selected a tentative entrance point from the CT scan, one should carefully inspect the chest at the

entrance site for several problems. First, if there are any obvious superficial veins noted, the site should be moved accordingly. Second, one should palpate deeply for the intercostal space between the margins of the ribs. It is important to note that the interspace between the ribs is greater the more anterior the location and less posteriorly (Fig. 61-40). The ribs become smaller as they approach the apex, making posterior approaches the most difficult in that area because of the narrow spaces and angle. Palpation of the ribs is necessary because the location of the intercostal space as seen on the CT scan is not reliable. The tapered margin of the rib and the oblique orientation of the rib as it traverses the imaging section produce considerable partial volume effect and discrepancy regarding the actual location of the intercostal space on the scan. The problem of identifying the location of the ribs is especially relevant to the anterior chest wall where the ribs are mostly cartilaginous and fuse together in an unpredictable pattern. Although it is true that one can use a needle or a guidance cannula to “drill” through a cartilaginous rib, I do not recommend this with CT guidance because if one drills through the cartilage, the pathway of the needle is fixed, thereby preventing corrective angulation. Also, the fixed needle cannot move with respiration, thereby making a small tear more likely if the patient moves the lung while breathing. In the lung as in other areas, the needle should be permitted to “swing” freely with respiration. Any time the needle is adjusted the patient should be asked to suspend respiration temporarily during the manipulation of the needle or removal of the stylet to prevent tearing of the parenchyma or a pneumothorax.

Another structure that should be carefully noted is the scapula. When approaching a lesion from the posterior chest wall, at any location, one should carefully palpate for the scapula. Although on first consideration one might think this would not typically interfere with a procedure, the tip of the scapula is tapered in two directions so the location of the tip of the scapula is “averaged out” so that what is seen on the scan does not correspond to the palpable tip on the patient. In some cases, the needle is deflected without the operator being aware of the problem. Also, in some cases the patient will slightly move the scapula into the path of the needle and deflect it sufficiently to preclude a successful needle placement.

Figure 61-47. A, This small lesion was being considered for a cutting needle technique because of the close proximity to the pleura. B, Bolus scan shows enhancement of an arteriovenous malformation.

Another important point is related to the infiltration of the local anesthetic at the entrance sight. When the area is anesthetized, it is important to infiltrate anesthetic through the subcutaneous tissues and down to and including the pleura. Adequate anesthesia of the pleura makes the procedure virtually pain-free and permits insertion of the needle without the patient moving because of pain. So important is this step of anesthetizing the pleura that as I perform the actual insertion of the needle, I stop the needle tip at the pleura to inject a small amount of anesthetic at the pleura and to check the final angle of needle insertion before entering the lung (Fig. 61-48). If a rib is inadvertently hit during the initial anesthetic administration, I give a small bolus of lidocaine on the rib; this prevents any recurrence of pain if that area is struck again during the procedure.

There are two methods one can use for a needle aspiration of the lung: a single-needle method or a coaxial method. With the single needle, the needle is started into the superficial tissues and a scan is obtained to verify its angulation. Once the correct angle is determined, the needle is inserted to the correct depth. The other method that should be used for deep or small lesions is the coaxial, short-guidance cannula method as follows: The guidance cannula is inserted into the chest wall and adjusted until it is directed toward the lesion. The Chiba needle is inserted to the correct depth, and sample is obtained (see earlier discussion on coaxial method).

Aspiration Needle

Because aspiration needles have been used for many years by numerous authors, one can reliably make a number of valid conclusions regarding their use. First, the needle caliber size appears to have little effect on the success rate of the procedures. Equivalent successes have been reported with a wide range of needle calibers, from

23 to 18 gauge. The pneumothorax rate has little relationship to the needle caliber, but the hemoptysis rate is directly related to the needle caliber. When needles smaller than 20 gauge are used, the hemoptysis rate is quite low. This was confirmed by Khouri et al,²¹⁴ who noted in his series that the hemoptysis rate was 21% with an 18 gauge needle but only 5% with a 20-gauge needle.

Several early reports by Sargent et al³⁴⁷ and Stevens et al described the effects of increasing the number of needle passes. Stevens et al^{371a} reported that a second needle pass increased diagnostic yield by 10% and a third needle pass increased it by 1.5%. Sargent et al reported that a second needle pass increased the diagnostic yield by an additional 5% and that the third needle pass increased the diagnostic yield by another 3%. Stevens et al reported that the pneumothorax rate more than doubled with two passes.

From the above data, one can understand how we arrived at our current method when I use a 20-gauge Chiba needle for an aspiration biopsy and routinely only take a single needle pass. I prefer to defer a second needle pass until after the results of the first pass are known, unless there has been a break in the technique. If the cytologist is available for a rapid stain interpretation, the patient will remain in the department until the results are known. If this service is not available, I still prefer to wait for the results instead of taking a second pass, because the 24-hour delay is a small trade-off considering the high success rate. If a technical error has been made or the final position of the needle placement is not satisfactory, then a second needle pass will be made at once.

Cutting Needles

In recent years, there has been a remarkable change in the acceptance of cutting needles, especially in the chest. Whereas there was remarkable controversy and conflict

Figure 61-48. These three scans (A to C) show the optimal approach for performing a biopsy. A, This scan shows the needle positioned adjacent to the pleura, not the bulging of the pleura produced by the injection of lidocaine. B, The needle was advanced into the lesion for the biopsy. C, Scan after removal of the needle shows small infiltrate in the lung, representing hemorrhage. Small amounts of bleeding like this are common and are of no significance.

when our group¹²⁰ published the first use of cutting needles in the chest, they have been extensively assimilated as a routine consideration for lung biopsy.

As strange as it may seem, I believe that the usage of cutting needles has actually extended too far relative to procedures of the lung. Some groups seem to prefer cutting needles in all cases of lung biopsy, but I still believe they should be selected when appropriate to ensure the greatest safety and accuracy.

The basic tenet of all biopsy procedures is to use the most appropriate device to achieve success and a low complication rate. In most cases, a solitary lung tumor is of only three cell types: adenocarcinoma, squamous cell, or small cell. Aspiration biopsy with the 20-gauge needle as noted earlier is appropriate.

When a mass is accessible and in the appropriate location, a cutting needle may be used judiciously. The most critical factor with any cutting needle procedure is that a bolus injection be performed prior to the procedure. Although infrequent, vascular lesions such as arteriovenous malformations or vascular sarcomas may occur and catraprophe can be avoided by aborting the procedure (Figs. 61-46 and 61-47).

If a lesion within the parenchyma is accessible and of sufficient size, then a 20-gauge cutting needle may be considered because the risk is no different than an aspiration needle. This assumes the size and location of the mass are adequate to permit complete placement of the cutting area within the lesion (see Fig. 61-43). In such case, the intervening lung has no additional trauma than a Chiba needle because there is no caliber difference or exposure of the traumatic tip to the lung.

One must be prepared to compensate for deflection and bending of the needle when the stylet is inserted. Benign lesions tend to be very hard and the surrounding lung does not provide much resistance. Such lesions may bend the stylet or deflect to the side (Fig. 61-49).

If a mass abuts against the chest wall, as was true in our first report, larger needles such as an 18 or 14 gauge may be used. Because no lung is traversed, there is no additional risk.

The cutting needle is clearly indicated, as we have previously noted, if there has been a failed aspiration procedure or suspicion of lymphoma or thymoma. Mesotheliomas are quite difficult to diagnose even with a large cutting

needle because the morphology varies little between benign and malignant lesions.

Important Planning Factors

Common sense dictates that several precautions be taken when planning the trajectory. These include avoidance of vessels, bronchi, and blebs. Although there are no data to support the following statement, it is quite clear that avoidance of vessels and bronchi, in addition to using a 20-gauge needle or less, has definitely decreased the incidence of hemoptysis. In my practice the incidence of hemoptysis decreased from about 20% to less than 1% with CT procedures. Penetration of a bronchi may produce a spasm of coughing, which in turn can produce uncontrollable lung movement and predispose the patient to pneumothorax, bleeding, or air embolism (see complication section). Penetration of blebs will obviously predispose the patient to an immediate severe pneumothorax; avoidance is therefore prudent.

Minimizing Pneumothoraces

In many cases one can minimize the possibility of a complication by looking carefully for a "safe pathway" through the lung to the nodule being biopsied. In such cases one might locate the attachment to the pleura or an area of fibrosis that can be traversed by the needle. By planning the trajectory through such an area, only a minimal amount of parenchyma is traversed and/or the fibrosis can serve to keep the layers of the pleura attached and thereby avoid a pneumothorax. By looking for a small amount of "fat" that may be tented at the pleura, one can usually distinguish between a mass that is simply adjacent to the pleura and one that has a fibrous extension. This type of approach is especially important in high-risk patients with pulmonary hypertension, severe restrictive disease, or other serious underlying pulmonary problems.

Two other factors that can minimize the incidence of pneumothorax are minimizing the pathway of lung crossed (Fig. 61-50) and using a pathway of through nonaerated lung. One of my colleagues, Dr. Locke,²⁵⁰ studied a series of 235 cases from our center and looked at the incidence of pneumothorax as compared with the distance of the lung traversed. The distances crossed with the corresponding incidence of symptomatic pneumothorax were 1 cm, 3.7%; 1 to 2 cm, 10.7%; 3 to 4 cm, 19%; and 5 to 6 cm, 44.4%. Because these measurements were taken from CT scans, they were quite accurate without errors in magnification; other authors who have not supported this relationship made their measurements from radiographs, which are more subject to error.

Since our last edition was published, other authors^{98, 208, 234} have confirmed the importance of lesion depth. All three of these groups indicated that lesion depth was the prime determinant of pneumothorax for CT procedures.

Our previous claim that traversing nonaerated lung would diminish pneumothorax has been documented. Recently, Haramati and Austin¹⁶⁶ showed quite convincingly that if aerated lung was avoided, the pneumothorax rate decreased significantly. They found that the pneumothorax incidence through aerated lung was 46% as compared with

Figure 61-49. Scan of a cutting biopsy of granuloma. Note the bend in the needle produced by the hard character of the mass.

Figure 61-50. A, This shows the difference in approach for two lesions that are almost identical. This scan shows a direct lateral approach, with the distance of lung being crossed of almost half of that in B. B, This biopsy approach traverses almost twice the distance of lung and increases the potential risk by almost a factor of 3, according to new data (see text).

0% through nonaerated lung. Stated differently, if there is an area of infiltrate adjacent to a nodule, one should intentionally traverse the consolidated area (Fig. 61-44).

Target Lesion Sampling

Choice of the target site is self-evident, but several points are worthy of emphasis relative to biopsy of nodules. If the nodule being sampled contains a small amount of calcification, the calcified area should be avoided and the adjacent soft tissue density targeted. If the nodule is cavitated, appears necrotic, or is quite large, the central portion should be avoided in preference to the peripheral area (Fig. 61-51). Some caution should be exercised in such a case to limit the penetration into the cavity portion as well as the vigor with which the sample is obtained. Early authors have claimed such cases are more likely to result in pneu-

mothorax and severe bleeding; this has not been our experience.

Patient Position

In most instances it is simplest to have the patient lie in the prone or supine position, but other positions might also be considered (see Fig. 61-22). As noted earlier, there might be an optimal choice of pathway taking into account the factors described. In such cases, access to the appropriate entrance site might be facilitated by placing the patient in the prone, oblique, or decubitus position.

If the lesion is small and moves with respiratory motion, it may be wise to put the patient in an ipsilateral decubitus position and insert the needle through a direct anterior or posterior approach. This position minimizes the motion of the ipsilateral diaphragm because of the weight of the abdominal organs against the diaphragm. This restriction of motion minimizes movement of the lesion and thereby simplifies the performance of the procedure.

Figure 61-51. CT scan shows biopsy of a large cavitated nodule. The periphery of the mass is targeted for best results. Some authors have suggested that in such cases a higher incidence of pneumothorax and hemorrhage exists.

Hilar Lesions

Hilar lesions are best sampled by bronchoscopy and should be percutaneously biopsied only as a second choice. The success rate for bronchoscopy is better and the complication rate lower than for percutaneous procedures. With percutaneous procedures, the length of the lung to be crossed and the proximity of vessels make the incidence of pneumothorax and hemoptysis more likely. If a bronchoscopy has been attempted unsuccessfully, a percutaneous procedure will be performed with the following guidelines.

Before the procedure, intense contrast enhancement of the vasculature should be performed to highlight the location of the anterior, lateral, or posterior approach to be taken. Unquestionably, with such lesions a coaxial short-cannula method should be used. This method is especially helpful because, as noted earlier, before the biopsy needle is inserted the guidance cannula predetermines the angle. With a long distance from the pleura to the hilum, a few

degrees in error will result in a large localization error centrally.

Apical Lesions

Careful planning for apical lesions is important because of the unique anatomy of the upper chest. Anteriorly, the brachicephalic vessels, mediastinal vessels, clavicle, and axillary vessels make the approach more difficult. Posteriorly, the scapula covers a substantial portion of the posterior chest. Avoidance is best accomplished by having the patient fully abduct the shoulder so that the scapula moves laterally. Careful palpation usually reveals the margin of the scapula. Another anatomic factor making the approach more difficult is that the ribs become smaller as one progresses from the midchest cephalad to the apex. It is usually easier to plan the entrance site so that the angle is also slightly caudal, which makes penetration of the intercostal space easier (Fig. 61–41).

Several final points should be made about unusual masses in the apex. Neurogenic tumors and lateral meningocele may occur in the posterior mediastinum adjacent to the neural foramina (Fig. 61–52). Neurogenic tumors are hard and painful in biopsy⁶⁷; only seldom can a diagnostic sample be obtained. Puncture of a lateral meningocele will yield clear fluid consistent with spinal fluid.

Pleural Lesions

Pleural lesion biopsies are difficult to perform fluoroscopically because as the lesion is turned perpendicularly

Figure 61–52. Rounded masses such as this by the neural foramina are likely to be of neurogenic origin. Lateral meningoceles yield cerebrospinal fluid on aspiration. Schwannomas such as this one yield diagnostic tissue when sampled by cutting needle, as noted here, but are painful during biopsy because they are attached to the nerve roots.

to the fluoroscope, it becomes en face and more difficult to see. With CT, sampling of such lesions is quite easy and actually provides considerable flexibility for needle selection. Of course, an aspiration needle can be used at any time; in those cases in which it is indicated, a cutting needle can actually be used for a more adequate tissue sample. Goralnik et al¹²⁰ reported that these cutting needles could be used safely for pleural lesions. She recommended their use when either lymphomas or unusual tumors such as mesotheliomas were suspected. Any of the automated biopsy devices can also be used if the size of the lesion is large enough to accommodate the length of the needle action.

Mediastinal Lesions

Before the use of CT only a few authors ventured to perform biopsy of the mediastinum using fluoroscopic guidance. With the refinement of CT techniques, however, CT is now the modality of choice and is commonly used for this area.³

Several limited studies by Lauby et al,²³² Jereb and Krasovec,¹⁹⁴ and Rosenberger³⁴¹ and Adler³ demonstrated the feasibility of mediastinal biopsies with fine needles guided by fluoroscopy. Weisbrod³⁹⁶ and Westcott⁴⁰² confirmed the benefits of fluoroscopic procedures but also noted some of the disadvantages and potential hazards. The most extensive series consisting of 100 patients was reported by Westcott. Although the results showed a 96% correct answer, there were 10 patients with vascular aneurysms that created some difficulty. Five of the patients were excluded from a biopsy because of a difficulty in evaluating the mediastinum. In another five cases, inadvertent puncture of aortic aneurysms occurred; in one patient a hemomediastinum developed.

Weisbrod et al³⁹⁶ also reported several important observations. In their series they noted that although aspiration needles were satisfactory for metastatic disease, the needles were less than optimal for lymphomas (see later section). They also reported one case of cardiac tamponade, which was successfully treated.

Since these reports, Adler et al³ and our own group have reported the preference for CT in guiding such procedures, which can be quite effective and safe if the appropriate guidelines are used. Anatomic approach for the mediastinum is slightly different, depending on the space being sampled and the approach used.

Mediastinal Anatomy and Approaches

The mediastinum is an exciting area for the application of procedures because in the early development of these techniques they were considered off limits for several reasons. With the evolution of imaging and its corresponding procedures, radiologists and clinicians have become confident of mediastinal anatomy and pathology. The reliability of anatomic display and refinement of the interventional techniques are such that finally procedures of the mediastinum are now commonplace. However, these procedures require considerable skill and should only be performed by the most skillful radiologists, who are well versed in anatomy and procedures.

As one would expect, performing procedures in the mediastinum is contingent on comprehensive and complete knowledge of the mediastinal anatomy. One must be familiar with virtually all variations so that inadvertent puncture of a vascular structure does not occur. Aberrant subclavian vessels, left-sided vena cava, and prominent azygos veins are the most likely variations to occur. Furthermore, appropriate use of bolus dynamic scanning is critical to ensure all vascular structures are well-defined. Although it is seldom that tumors are vascular and represent a bleeding risk, it is not uncommon for vascular anomalies, aneurysms, or pseudoaneurysms to exist (Fig. 61-53).

Procedures of the different portions of the mediastinum (superior, anterior, middle or posterior) require uniquely different approaches for such procedures. Successful and safe procedures in these areas require careful attention to the subtle techniques used to guide and manipulate instruments in these areas.

Superior Mediastinum

The superior mediastinum consists of the space above the aortic arch and contains the various brachiocephalic vessels (venous and arterial). This is the most common area for congenital variations because arteries emanating from the arch and venous variations are quite common.

This space requires an anterior insertion in virtually all cases and usually results in an approach through the suprasternal notch or the parasternal region (Fig. 61-54). In all cases a good vascular study with bolus injection is critical to clearly define the carotids, jugulars, and small vessels (Fig. 61-53). In most cases the lower portion of the thyroid gland and the trachea must be dealt with to approach such masses. As a matter of course it is always critical to identify clearly the lobes of the thyroid, because it is common for substernal or low-lying thyroid to be mistaken for a mass in the upper mediastinum. If the ipsilateral lobe of the gland is not identified, one should always consider the possibility that the observed mass might be the lobe of the thyroid.

The methods for choosing the correct entrance site and pathway are essentially the same as the other areas. As the needle is inserted, the pathway and tip of the needle are carefully monitored with incremental adjustments. Use of the bevel to slide past the different structures is important to provide clearance around the vessels. As noted in the earlier technical section, the bevel is turned toward the structure to be avoided and the point is rotated so that it is directed toward the intended target. Also as noted in earlier sections, successful maneuvering of the needle around a vessel or structure is best accomplished by pushing the instrument slowly, which facilitates the deflection of the needle.

Anterior Mediastinum

Lesions in the anterior mediastinum are in the anterior space behind the sternum or anterior to the aortic arch. In the vast majority of cases, one can access these lesions by using an insertion site just lateral to either side of the sternum. One must be cautious to not sample the internal mammary artery or vein. With these lesions one can use either an aspiration or cutting needle as in other portions of the mediastinum. Careful localization of the cutting

Figure 61-53. Common vascular variations are noted in these three images, which of course should not be mistaken for tumors; distinction is quite easy with contrast material. A, This scan shows a very prominent azygos vein. B, Scan at the level of the arch shows a small aneurysm, at the ductus region (D). C, Scan of the upper mediastinum shows an enhancing mass behind the trachea, which represents an aberrant subclavian artery.

Figure 61-54. A, The most cephalad portion of the superior mediastinum includes the brachiocephalic vessels. This shows a mass (long arrow) adjacent to the subclavian artery. A needle (horizontal arrow) is inserted through the suprasternal notch and carefully advanced into the mass. In such cases it is best to keep the bevel directed toward the vessel so it will skim over the surface of the vessel. B, A different patient with a small mass posteriorly, adjacent to the esophagus and trachea. A needle is noted passing by the trachea. The bevel of the needle was directed toward the trachea.

needle gap is critical in such cases (Figs. 61-55 and 61-56) because cutting of the major vessels would certainly be catastrophic. As noted in the earlier section, placing a patient in a lateral position can shift the anterior junction line to make such procedures simpler. Gupta et al¹³³ have

proposed using a trans-sternal approach with a coaxial system; these authors advocate using a coaxial cannula to penetrate the sternum and use a needle through the cannula. I have not found the need for this approach and have preferred to use the methods discussed here.

Figure 61-55. A, CT scan shows an ill-defined mass in the anterior mediastinum, believed to be subtle mass in thymus. With the patient in the prone position, access to the mass cannot be obtained without crossing the lung. B, When the patient is positioned on the side the mediastinal structures shift, permitting access for needle placement into the mediastinum.

Figure 61-56. A, Biopsy of anterior mediastinal lesions can be safely performed if the edge of the anterior space abuts the pleura and there is sufficient space to avoid the lung. Also, as noted here, it is critical to perform a bolus injection to distinguish opacified vessels from lymph nodes. B, Lymph node biopsies can be safely performed if the cutting needle "gap" can be confined to the node (arrow).

Figure 61-57. A, A mass (m) located in the azygous region shows tumor posterior to the cava and aorta. Initial positioning of needle required slight direction medially. B, A Chiba needle, within the coaxial cannula, is pushed past the vessel with the bevel directed toward the vena cava. C, Through the cannula, a Chiba needle aspiration was performed. D, After removal of the Chiba needle, a cutting needle (20 gauge) procedure was performed.

Figure 61-58. A, A mass (M) is located lateral to the trachea. Note the marker on the skin surface (arrow) used to choose the entrance site. B, The pathway for the needle (arrow) is most appropriate when it traverses the juncture point between the transverse process and the rib. C, By using ample local anesthetic along the ribs and paraspinal path, the needle (arrow) can slide along the vertebral body and enter the mass.

Middle Mediastinum

The middle mediastinum is a rather large space below the arch and encompasses the azygous node (Fig. 61-57), peritracheal region (Fig. 61-58), aortic pulmonary window (Figs. 61-59 and 61-60), subcarinal region (Fig. 61-61), and the periesophageal region (Fig. 61-62). The peritracheal regions and the aortic pulmonary windows are typically best approached by an anterior approach through the anterior junction line while avoiding the lung parenchyma

and other structures. It is worthwhile to recall that the internal mammary vessels should be identified prior to any procedure so that the entrance and pathway can be planned appropriately to avoid these structures.

The anterior approach may be performed if the patient has a wide anterior junction region, but in many cases it is helpful to place the patient in a lateral position, either on the right or left side. By doing this, the anatomy may shift so that a clear pathway through the anterior fat space may be possible, thereby preventing any possible pneumothorax

Figure 61-59. A, Scan during bolus injection shows enhancement of the aortic arch (A). The mass (M) in the aortic pulmonary window of the middle mediastinum is clearly seen. B, Because the anterior junction is quite wide, insertion of the Chiba needle is quite simple. C, With the precise visualization of the margins of the cutting needle, accurate placement of the gap and sampling of the mass are easily accomplished. Because the action of the needle is confined to the gap, there is no risk of damage to the aorta.

Figure 61-60. A, Access for this biopsy was not present when the patient was lying supine (see Figure 61-9A and B). The path of the needle was not appropriate for sampling a small lymph node (arrow). B, The needle was redirected using the deflection method described and demonstrated earlier. The node was sampled without removal of the needle and redirection.

Figure 61-61. A, The middle mediastinum shows a mass (M) clearly distinguished from the opacified vessels. The method shown here is effective for consistently sampling such masses. B, The needle is inserted at a point where the trajectory crosses the junction between the transverse process and the rib. Saline is injected into the paraspinal tissues, moving the pleura more laterally, facilitating easy passage of the needle. C, This scan shows the next step in the procedure, which consists of positioning the needle against the anterior lateral margin of the vertebral body. The bevel of the needle is directed toward the body; the needle is pushed forward close to the aorta. D, When the needle is against the aorta, the bevel is turned toward the aorta and pushed forward past the aorta. E, At this point, the bevel of the needle is turned toward the azygos vein and pushed forward. F, The final positioning of the needle is within the mass.

Figure 61-62. A, A patient with a history of hepatoma shows a mass (M) in the middle mediastinum lateral to the esophagus. The lidocaine needle is used to inject saline in the paraspinal space, enlarging the pathway; compare to the opposite paraspinal space (arrow). B, An aspiration needle biopsy is performed. Performing such aspiration needle biopsies prior to cutting needle permits assessment of pathway clearance and cooperation of the patient. C, The cutting needle has been inserted after aspiration biopsy and the stylet inserted. Note that the gap is rather medial, and it was considered too close to the esophagus. The stylet was retracted and the needle rotated 180 degrees. D, Using the deflection of the bevel of the stylet, the gap is more laterally positioned so that the sample could be taken without a major readjustment of the needle. Note the position of the gap compared to that in C.

that could occur if the lung were traversed (see Fig. 61-59). In such cases injection of saline or gas may be helpful to slightly enlarge the potential pathway (see Fig. 61-60). The widening of the pathway is typically quite small because these materials disperse along the long axis of tissues as well as the cross-sectional areas, so the change in the anatomy is usually minimal. Maneuvering the instruments

past corresponding vessels is a critical part of the procedure.

Paratracheal or azygous lymph nodes can be approached by traversing the anterior mediastinum and the space between the superior vena cava and the ascending aorta. The level of entrance is below the origins of the brachiocephalic vessels and the subclavian veins. When using this ap-

proach, it is critical to choose the correct entrance site and trajectory to ensure uneventful passage of the needle past the vessels. Traversing the space between the cava and aorta is simpler if the process has slightly widened the space. In those cases when the vessels have not been separated in this fashion, the successful placement can be accomplished by using a coaxial system as follows. With the newly designed devices, blunt or rounded stylets are available so that the walls can be pushed slightly and penetration avoided. In other cases, one might choose to use a small-caliber bevel needle to slide between the two structures, and the coaxial cannula can then be advanced over the Chiba needle (see Fig. 61–57).

The subcarinal area is best approached through a posterior paraspinal approach from either the right or left side depending on the location of the mass. Surprisingly, the left approach between the aorta and the vertebral body is usually the best approach because there is more space compared to the paraspinal region on the right side (Figs. 61–61 and 61–62). As one reviews the provided figures, the approach seems almost unbelievable but the truth is that I have consistently performed this approach for 15 years with no complications. From my perspective, it would be gratifying to believe I was the only one capable of doing this, but the facts are that the approach and methodology are valid and most experienced and motivated interventional radiologists can learn to perform this procedure.

Choice of the correct pathway and entrance site is critical to the success of the procedure. The most suitable trajectory from which an entrance site must be chosen is a pathway that includes the margin of the transverse process/rib junction, the margin of the vertebral body, and the mass itself. The trajectory path should not include any vessel. A small amount of lung parenchyma in the path is acceptable but not preferable.

Selection of any other pathway more medial than this will not be successful for the following reasons. The contiguous overlap of the transverse process and the rib articulation provides an almost impenetrable “shield” that is painful and traps the needle so that no angulation or adjustment is possible.

When this technique is executed, ample use of local anesthetic is important in not only the skin but also at the site of the transverse process and the vertebral body. These two additional sites are painful because of the periosteum unless adequately anesthetized.

The various steps of the procedure are as follows. The site is prepared and the needle is advanced just to the margin of the transverse process. At this level, local anesthesia is infiltrated on the periosteum. The needle is rotated so the bevel is turned against the body and the needle pushed slowly. The tip of the needle is located closely to the margin of the vertebral body and local anesthesia is injected. The needle is adjusted if needed so that the bevel of the needle is against the edge of the vertebral body and pushed slowly several millimeters. The bevel is then rotated so the bevel is toward the aorta and pushed forward 4 to 5 mm to pass the aorta. If the hemiazygos vein or esophagus is close, the bevel may also be adjusted to pass by those structures. Once positioned in the mass, the sam-

ple is acquired as appropriate with either the aspiration or cutting needle.

The sequence of events in this procedure will typically proceed predictably, but it can be aborted any time at the judgment of the operator. As one begins to learn this technique, each succeeding attempt provides additional confidence that enhances eventual success and comfort with the procedure. One almost insurmountable difficulty is the presence of a large osteophyte that may occur at the edge of the vertebral body. When a large spur is present, one might not even choose to attempt the procedure. If the procedure is being performed and an obstruction occurs at the edge of the vertebral body, minor adjustments of the needle can be made to determine if passage is possible. Persisting beyond several attempts is seldom beneficial.

Posterior Mediastinum

Sampling abnormalities in the posterior mediastinum is much easier than either the anterior or middle mediastinum. The posterior mediastinum represents the space adjacent to the vertebral body and the pleura region. In most cases, there is clear access to the mass without crossing the lung parenchyma. In such circumstances it is usually most expeditious to perform a quick sample with an aspiration needle and then follow it with a cutting needle. Performing the aspiration first permits one to ascertain the effectiveness of the local anesthesia and the cooperation of the patient prior to using the cutting needle (see Fig. 61–42).

Pneumonias and Infiltrates

Recovery of samples for culture and identification of infectious processes has become more popular in recent years. The results have been somewhat variable for the routine pyogenic infections, so we have seldom been asked to sample such problems. The opportunistic infections in immunocompromised patients have become a more significant diagnostic dilemma, and thus the occasion may arise in which sampling is more critical.

In our experience the diagnosis of fungal infection with cavitation or fungus ball by needle aspiration is quite reliable and easy to perform. In such cases, the procedure is performed in a standard fashion, except that the sample is sent for appropriate stains and culture.

When a more difficult pathogen such as *Pneumocystis carinii* is suspected, simple aspiration may not suffice. Although some authors have inferred that recovery of diagnostic tissue is quite easy, we have found that it is not. In many cases one may require a small cutting sample that can provide more ample material for evaluation. When the infiltrate abuts the pleural membrane, we have employed a small cutting 20-gauge needle with considerable success and no morbidity. Our experience is quite limited (to perhaps 10 cases), but we are optimistic for this technique.

Results: Success and Complications

The success rate of lung biopsies has varied widely among the many reports of fluoroscopic and CT-guided procedures. These rates have ranged as low as 60% and as high as 95%.

In our experience, the success rate is about 75% with a single pass and overall 85% with a second pass as required. These results are exclusive of lymphoma and mesothelioma cases, which are very difficult to diagnose with aspiration biopsies. Weisbrod et al³⁹⁶ noted that in about 67% of cases the diagnosis of lymphoma can be suggested, but not the definitive subtype. Goralnik et al¹²⁰ found that the specific subtype could be diagnosed using a large cutting needle for suspected lymphoma lesions.

Although it is true that the outcome may vary from one institution to the next depending on the selection criteria for patients, favorable results can be obtained with the careful attention to detail and technique as noted in this chapter.

Reliability of Aspiration and Cutting Needle Results

Several reports by Sinner et al,³⁵⁶ Thornbury et al,³⁸⁰ and Greene¹²⁴ have documented that the results of aspiration biopsies correlate well with histologic results. Green et al¹²⁴ found the correlation to be 92.3% for adenocarcinomas, 100% for squamous cell, 88.9% for large cell undifferentiated, and 100% for small cell undifferentiated. Taft et al³⁴⁵ found an interobserver error to be only 6% with 94% overall consistency.

The consistency for diagnosing lymphomas is much less. Weisbrod et al³⁹⁶ and Westcott et al⁴⁰⁰ have shown that aspiration biopsies are capable of suggesting the diagnosis of lymphoma, but Goralnik et al¹²⁰ showed that only a cutting needle biopsy was capable of providing the definitive subtype of lymphoma.

Cutting Needles

Since the prior edition of this book, there has been considerable data presented about the use of cutting needles for lung biopsies. The consensus supports our previous position on the use of aspiration and cutting needles. In the vast majority of patients with common neoplasms of the lung, the cutting needle offers no definite benefit. In those cases when a failed aspiration biopsy has been performed, suspicion of a benign or unusual tumor such as thymoma or lymphoma is suspected, a cutting needle appropriately used provides considerable benefit.

Numerous authors, including Kushihashi et al,²²³ Laurent et al,²³³ Rotte,³⁴³ Greif et al,¹²⁷ and Klein et al,²¹⁷ have verified the usefulness of the cutting needles but confirm the role of aspiration needles. Klein et al found little difference in the diagnosis of malignant lesions but great superiority for benign disorders. The correct diagnosis with benign lesions was 44% with aspiration needles and 100% for cutting needles. Greif et al found little difference in the diagnostic accuracy for malignant lesions but considerable benefit for benign disease. With peripheral lung nodules, Greif et al reported an accuracy of 81% for benign lesions compared to 16% for aspiration needles.

For the unusual malignant and benign tumors, multiple authors have shown the improved results with cutting needles. Carruthers et al⁴⁷ reported the usefulness of cutting needles for diagnosing Wegener's granulomatosis. Greif et al¹²⁷ reported that in the mediastinum, the cutting needles could diagnose lymphoma, thymoma, and bronchogenic

carcinoma accurately. Zinzani et al⁴¹⁹ reported on a series of 83 patients, in which the accurate diagnosis of lymphoma was achieved in 81%. Lopez et al²⁵¹ reported a 93% accuracy for the diagnosis of benign lesions.

Mesotheliomas are also quite difficult to diagnose with any type of needle. In our experience with about eight such cases, the diagnosis of mesothelioma can be suggested, but the differentiation of benign versus malignant cannot be made even with cutting needles.

The most difficult question to be resolved relative to these procedures is the significance of a negative or benign diagnosis. Some authors have suggested that because they obtained a "negative" aspiration for malignancy from a benign lesion, the correct diagnosis could be inferred. This is obviously not the case, for one must always be suspicious of a negative aspiration unless other information is available. It is difficult to accept that authors correctly made the diagnosis of granulomas, sequestration, and other unusual benign lesions based solely on aspiration biopsy. As Westcott noted, it is appropriate to accept a specific result that states a diagnosis (e.g., hamartoma, infarct), but claims of the recovery of histiocytes, leukocytes, and other nonspecific cells should be regarded with skepticism.

It is only after several repeat biopsies that yield nonspecific material that one can consider following such a lesion. If there is a strong history of family disease or smoking, it is appropriate to have surgical removal of such a lesion regardless of the results.

In patients without risk factors, one may choose to follow such cases at 3-month intervals, for a total of 9 months. If such a lesion is benign, it will usually shrink or calcify during this period. If there is any increase in size, then surgery should be performed immediately. At the end of 9 months, if there has been no change, it is appropriate to re-evaluate the case.

Success Factors

A number of factors improve the probability of a positive biopsy. These factors include the operator's experience and technique; pathology; needle type; and character, size, and location of the lesion. Experience of the cytologists and pathologists is important. The greater the experience, the more consistent the results of the procedure. Proper technique includes choice of appropriate needle and maintenance of proper vacuum.

It is always important to include the routine slide smears as well as a saline rinse of the needle and syringe for submission to pathology; a cytocentrifuge and cell block preparation will increase the diagnostic yield of such samples. Pathologic results depend on the cell type of the tumor as noted in the results section; the common primary lung tumors are easily diagnosed, whereas others are not.

The size and location of a mass affect the probability of a positive diagnostic aspiration. Bergquist et al³⁰ noted that the diagnostic accuracy was higher for larger lesions and for more peripheral lesions. For example, a 1-cm nodule was successfully biopsied in 58% of cases when it was central; it was successfully biopsied in 85% of cases when it was peripheral. More recently, two additional authors, Li et al²⁴¹ and Miller et al²⁷⁸, have confirmed the improved diagnostic recovery from large lesions compared to smaller ones.

Postprocedure Care

The postprocedure care of these patients is quite simple and consists of observing them for severe hemoptysis and pneumothorax. Immediately after completion of the procedure, I prefer to have the patient lie still for 5 to 10 minutes to let the puncture site seal. Moore et al¹²⁸⁶ have shown that if the patient is positioned with the puncture site down after the procedure, the incidence of pneumothorax is reduced. The pneumothorax rate for patients placed in this position was 17.9%, whereas the rate was 33.6% for those not so positioned. Chest tube rate was 9.8% for those who were correctly positioned, compared with 0.4% for those who were not.

Before removing the patient from the table, I take a repeat scan to evaluate for postprocedural problems. Miller et al²⁷⁹ have shown that CT is as reliable for detecting pneumothorax as is a plain radiograph. A small pneumothorax is of little significance, as noted later. Some bleeding in the parenchyma in the area of the needle tract is quite frequent, but it is of no significance. If there is any question of the patient's stability, oxygen should be administered and appropriate treatment given, as noted later.

Postprocedure chest films should be taken at 1-, 4-, and 8-hour intervals. Perlmutter et al³²⁶ showed that pneumothoraces could be detected in the following percentages at the noted timed delays: 89% immediately after procedure, 9% after 1 hour, and only 2% after 4 hours.

The most frequent complication is pneumothorax, which can be easily treated with a small-caliber tube and a one-way valve. The decision to insert a chest tube is dependent on patient symptoms, patient attitude and attending service, and patient reliability. In the best of circumstances, the chest tube is inserted only if the patient is symptomatic. Even a 50% pneumothorax does not require treatment unless the patient is symptomatic. If there is any question

of the patient's symptoms, reliability, or housing status, the chest tube should be inserted.

Chest Tube Insertion

It is best for the inexperienced operator to insert the chest tube under fluoroscopy or at the table side, depending on the experience of the interventionist and the distress of the patient.^{325,337} The placement of the chest tube is quite simple and can be accomplished in the following fashion. One should use an entrance site in the anterior second or third intercostal space on the side of the pneumothorax. After preparation of the site with antiseptic solution, one should thoroughly anesthetize the site down to and including the pleura. One can estimate the depth required for the tube insertion by using the anesthetic needle to aspirate air at the site (Fig. 61-63).

After administration of the anesthetic, a nick in the skin is made with a scalpel to provide ample space for the tube. As one pushes the tube through the chest wall, a "give" is noted; this indicates passage through the pleura. The tube is kept perpendicular relative to the axial plane until it passes into the pleural space. It is then angled slightly cephalad so the tube will lie in the apical lateral region. This location is optimal because in this position it will evacuate "rising" air when the patient is either lying down or standing up.

After placement of the tube, one should always reconfirm the proper location of the tube, even if the placement was optimal. This can be done by checking the tube position with oblique or lateral films. Another method one can use is to place the end of the valve close to one's ear and listen for the escape of air through the valve.

After the placement of the tube, patients will usually experience some pain as the lung reexpands against the

Figure 61-63. A, Disposable chest tube trays such as this are available. These are complete and provide all necessary equipment, including the instruments, tube, and Heimlich valve. B, This chest film shows the chest tube in the left upper lobe. Whenever the tube is positioned, one should clinically check for the egress of air to ensure proper function.

tube. A mild analgesic will relieve the discomfort; repeat analgesics are seldom necessary.

At this point a complete explanation should be provided to the patient and nursing staff to prevent inappropriate or premature closure of the tube.

If the lung is reinflated for 10 to 12 hours, the tube can be removed. The tube should be clamped for several hours and a repeat film taken. If the lung remains expanded, it can be removed. If not, the valve should be reopened for 24 hours and the procedure repeated at a later time. If severe primary lung disease is present, expansion could take as long as 2 to 3 days.

Complications and Causative Factors

Pneumothorax

The pneumothorax rate reported for CT procedures varies widely among patient groups. The asymptomatic rate varies between 17.5% and 72%. The symptomatic rate, requiring chest tube, varies between 6% and 18%. Our rates using the single-needle method and the coaxial, short-cannula method are 17.5% for asymptomatic and 6% for symptomatic pneumothoraces. The higher rates reported by other authors are probably the result of the prolonged time of the procedures and the multiple needle punctures associated with the tandem-needle technique.

Some authors attribute the high pneumothorax rate to the prolonged length of the procedure. They reported the average period for the needle to be within the lung parenchyma as 15 to 20 minutes. This compares to the average of 6 minutes we tabulated in our department. The difference we believe is related to patient selection, preplanning, proper needle selection, and technique.

The risk of a pneumothorax also depends on many other factors, including status of the lung, number of needle passes, and length of pathway through aerated lung penetrated. Fish et al⁹¹ and Miller et al²⁷⁹ showed a definite relationship of pneumothorax to lung disease. Fish et al evaluated chest films and spirometry to determine the presence of chronic obstructive pulmonary disease (COPD) and found that normal patients had a pneumothorax rate lower than those with COPD. With spirometry measurements the ratio for pneumothorax was 45% for COPD patients, compared with 25% for normal patients. Using the chest x-ray examination as the standard, the rate was 42% for COPD compared with 25% for normal patients (see earlier section on minimizing pneumothoraces).

Hemoptysis

The rate of hemoptysis is quite low with all types of techniques and appears to be dependent only on needle size. In a series by Khouri et al,²¹⁴ the hemoptysis rate for 20-gauge needles was only 5%, compared with 21% for 18-gauge needles.

The other factors affecting hemoptysis are the depth of lesions, coagulation status, and presence of congestive failure. Deep lesions or hilar lesions are at greatest risk because of the long pathway and proximity of blood vessel. Those patients with coagulopathies, pulmonary hypertension, or congestive heart failure are at greatest risk for

hemoptysis and even endobronchial bleeding (as noted later) and should be biopsied without correction of the basic problem. Commonly, localized hemorrhage in the parenchyma may occur following a biopsy, but it is of no significance.

Fatalities

As seen in the original articles describing fatalities, the two causes are endobronchial bleeding and air embolism. I have been able to locate nine reported deaths in the literature—five from endobronchial bleeding and four from air embolism.

Endobronchial bleeding is a rare event. In my opinion its occurrence is based on the nature of the abnormality being sampled as well as on needle caliber.^{280,305} Although deaths have occurred with both 22-gauge and 18-gauge needles, it is quite clear that the rate of hemoptysis is less with small-caliber needles. The cases reported in the literature were associated with ill-defined masses adjacent to the hila. Also, however, one must remember the importance of bolus studies in selected patients (Figs. 61-46 and 61-47).

Those cases of air embolism were associated with coughing paroxysms. Several authors^{381,400} hypothesized that the air embolism is a result of the elevated intrabronchial pressure that occurs with coughing; the high-pressure air follows along the needle track into the blood vessels. One should avoid the temptation to "counsel" the patient not to cough. To avoid such problems, one should immediately remove the needle if a patient starts to cough during a procedure. Patients with a propensity to cough should be treated with codeine before attempting a biopsy.

Blood-Patch Technique

Several authors have reported on the blood-patch technique, which is used to reduce the possibility of a pneumothorax.^{35, 172,267} With this method a coaxial needle method is used and a blood clot is injected through the long cannula during its removal from the lung. The results of this method are variable, and Bourgouin et al³⁵ reported no difference in outcome when it was evaluated in a randomized prospective fashion.

Liver Biopsy

Liver biopsy is a common procedure* because the liver is commonly involved with malignant processes and benign disorders that can mimic malignancy. Because specific differentiation of these various processes is not possible by imaging methods, definitive diagnosis by biopsy is necessary for planning proper patient management and avoiding unnecessary surgical procedures. A new era of treating disease focally has also begun (discussed later).⁷⁶

Indications

The indications are quite broad considering the diagnostic and guidance accuracy of both ultrasound and CT. Any

*References 258, 265, 369, 370, 398, 404.

patient with a focal hepatic mass or unusual anatomic configuration should have a guided rather than a blind procedure.

Diffuse processes of the liver are probably best performed by the blind method at the bedside, but any blind procedure that has failed is an indication for a guided procedure. Those associated with large amounts of ascites are best served by a guided procedure because the presence of fluid makes percussion of the liver edge quite difficult, so bedside procedures are compromised. The other indication for CT guidance is the need for the use of a 14-gauge cutting needle. Although the use of smaller cutting needles such as a 20 or 18 gauge is somewhat commonplace with ultrasound, the large size of the 14 gauge dictates the use of CT. CT is the best modality for characterization of lesions and visualization of the anatomy and the needle. When a radiologist becomes experienced, one can perform biopsies on a routine basis with considerable success and low complication rate⁷⁵ (see section on new cancer initiatives).

Biopsy of patients with abnormal coagulopathy should be performed under a combined guidance procedure, both imaging and fluoroscopy, so that special hemostatic techniques as described later can be used.

The choice between ultrasound, MRI, or CT must be made by the individual physician, but in general, CT is still considered the gold standard. Difficult anatomic location, poor visualization under ultrasound, or concern about increased vascularity is a clear indication for CT guidance. In some cases, lesion may be only visible on MRI, so the modality of choice is probably MRI.

Selection of Needle

For the liver, I use either a 20-gauge Chiba needle for an aspiration cytologic sample or a Tru-Cut needle of 18- or 14-gauge caliber. Selection of a needle is based on clinical factors, anatomic characteristics, and bolus contrast enhancement.

From a clinical perspective, a previous history of a malignancy is sufficient evidence to consider using only an aspiration needle. In the vast majority of cases the cytologic sample is quite adequate to confirm a previously diagnosed tumor.

A number of anatomic factors dictate the need for an aspiration biopsy. Unusually close proximity to various structures such as the vena cava, hepatic vein, portal vein, gallbladder, pleura, or diaphragm indicates the need for an aspiration biopsy.

Concern about a possible hemorrhagic complication is also an indication for an aspiration procedure. Such concern is typically raised if a coagulation problem exists or if a lesion is suspected of being vascular. A small abnormality in the coagulation studies is sufficient to justify the use of an aspiration needle. Bolus contrast enhancement is useful for assessing the vascularity of lesions. Those lesions that are slightly vascular should be sampled by an aspiration needle because it is safer than a cutting needle. If a lesion is highly vascular, one probably should not even use an aspiration needle (see later section on hepatoma) (Fig. 61-64).

Figure 61-64. Diagnostic scan on patient with colon cancer shows a highly vascular lesion in the left lobe of the liver. This lesion is so vascular that no biopsy should be performed with standard methods (aspiration or cutting).

The larger cutting needles, either 18 or 14 gauge, can and should be used if a lesion is unknown, accessible, and avascular with a contrast enhancement. When an abnormality is unknown, only the sample obtained with the cutting needle can provide the type of histologic detail for the definitive diagnosis of virtually all benign and malignant lesions (see later sections on results).

New Cancer Initiatives

In recent years with the development of new sophisticated treatments for cancer, a new approach for cancer drug development and treatment has evolved based on acquisition of biopsy tissue. These initiatives have focused on the ability to measure molecules and microchemistries of tissue samples to assess the end-target effectiveness. The protocols that have been used for limited early drug development will be expanded to enhance new treatment approaches to include DNA, RNA, peptides, cytokines, and so forth. It is likely that these approaches will enter everyday clinical practice and that tissue sampling and testing will become the mainstay for drug selection and determination of efficacy.

The protocol for drug development has been that a large-caliber (14-gauge) needle is used to sample target tumor tissue prior to drug administration and at selected times following drug administration. From the tissue samples, microassays are performed to determine the presence and effectiveness of the administered drug. Using these methods, remarkable findings have occurred that have revolutionized the outcome of such studies. Probably the greatest testimony to this trend is the change in the vernacular for cancer therapy. Whereas previously researchers would talk about the maximum tolerable dose (MTD), they now talk about optimal modulatory dose (OMD) of the chosen drug or modulating agent.

In the future it is very likely that cancer patients will

receive repetitive biopsies over the course of their treatment to assay drug, change drug therapy, and modulate treatment based on such samples. The approach will not be dissimilar to that of sampling and treatment of infectious agents that occur in abscesses or blood cultures.

The reason this topic is discussed in this section is that the success of this new approach is contingent on obtaining sufficient tissue for assays, which depends on the use of larger needles such as the 14 gauge. These approaches are clearly the direction of the future, so it is imperative that radiologists learn the best techniques for performing such procedures. Because of our experience over the past 25 years, we are confident that our approach can provide a sound basis for further expansion of these methods.

Contraindications

There are several contraindications to liver biopsy. Severe uncorrectable coagulopathy is the most common contraindication; if an abnormal baseline exists and it can be corrected with fresh frozen plasma or platelets, the procedure can be performed without additional precautions. If an abnormal baseline cannot be corrected, other steps must be taken as described later in the section on hemostatic techniques.

Lack of patient cooperation is a relative contraindication. If a patient cannot cooperate with sedatives, then general anesthesia might be considered.

Another contraindication is the presence of increased vascularity or prominent vascular collaterals as noted with contrast enhancement. Those lesions, which may be vascular, include focal nodular hyperplasia, hepatomas, hemangiomas, sarcomas, and metastases (Figs. 61–64 to 61–66).

Aspiration Biopsy

For aspiration biopsy, either the single-needle or coaxial method using the 20-gauge Chiba needle should be used.

A number of factors should be considered regarding entrance site selection and preparation, trajectory planning, target selection, and follow-up.

Entrance site selection is based on the location of the lesion. Generally, the shortest pathway that avoids the portal venous system, gallbladder, bowel, and diaphragm should be chosen. To avoid the pleural space, one should choose a site below the insertion of the diaphragm. If the lesion is somewhat high, this can be most practically accomplished by choosing a site no more posterior than the midaxillary line. When the lesion is high in the liver above the insertion of the diaphragm, an angled approach is necessary. The anterior diaphragm is much higher than the posterior portion, and lesions are more easily approached without crossing lung.

If the lesion is mobile, the patient can be placed in either a decubitus or oblique position to help immobilize the lesion.

Careful palpation of the site and preparation are important. Avoidance of ribs can be accomplished by palpation. To make the procedure completely pain-free, the pathway should be anesthetized from the skin down to the capsule of the liver.

For the best results, the pathway should include a cuff of normal liver. This cuff can help prevent leakage of blood or tumor cells into the peritoneum (Fig. 61–67).

Target selection is fairly straightforward. One should choose the lowest lesion that is easily approachable. If the lesion appears quite necrotic, one should attempt to position the needle within the periphery where one would expect more viable tissue.

The needle procedure is the standard aspiration procedure as previously described. We use the standard application of suction and reciprocating motion and two passes.

After the procedure, minimal follow-up is required. For patients who have not had a complicated procedure, we typically undertake an observation period of 1 to 2 hours.

Figure 61–65. Hemangioma is a fairly common benign problem that has the potential for catastrophic bleeding. *A*, This scan was taken during the contrast phase and shows the characteristics of feeding vessels in the wall of the lesion. *B*, Late-phase scan shows the mass to be completely homogeneous in the delayed phase. These qualities are pathognomonic, and no procedure should be performed.

Figure 61-66. The definitive qualities of the bolus assessment of vascular lesions can be demonstrated by this highly unusual case. This series of scans (A to F) show the images of an "atypical hemangioma" that does not show the typical qualities. Such lesions are partially thrombosed and have very small capillaries so there is no significant increased blood flow perceptible. A, This scan shows a low-density mass (M) in the right lobe of the liver. B, Later scans did not show typical enhancement but did show homogeneous appearance in the late phase. C, T2-weighted image shows a large image with inhomogeneous intensity, not completely characteristic with hemangioma. D, Because there was still concern about hemangioma, an angiogram was performed. This early-phase image shows hepatic vasculature but no increased vascularity. E, Late-phase angiogram shows no evidence of "puddling," said to be characteristic of hemangioma. F, A 14-gauge biopsy of the lesion shows a gap centrally in the lesion. Pathology reports showed hemangioma. The point is not that biopsy should not be performed in hemangiomas but rather that the bolus study is so sensitive to blood flow that if a lesion is avascular with this method, one can perform a biopsy of an unknown mass with confidence that there will be no bleeding. Rarely, such avascular masses will ultimately prove to be atypical hemangiomas.

Figure 61-67. This figure demonstrates the typical approach for a liver biopsy. *A*, This image was taken during a bolus injection and shows the masses (M) in the liver that are not vascular. (A marks the aorta). *B*, Scan shows the preliminary insertion of a small-caliber needle, which was used to anesthetize the capsule of the liver as well as provide an aspiration sample from the mass. This quick needle aspiration provides useful information about the status of the anesthetic and the cooperation of the patient. *C*, This final scan shows the cutting needle localized to the mass; the gap is clearly visible.

Cutting-Needle Biopsy

Cutting-needle biopsy is performed using the single-needle technique and the techniques described previously. The most commonly used needle is the 14-gauge Tru-Cut type, but occasionally we use an 18- or 20-gauge Tru-Cut needle. Most commonly I use the manual Tru-Cut needle, but in some circumstances I use the automated biopsy gun.

Routinely, I prefer a single pass of a 14-gauge needle rather than multiple passes with smaller-gauge cutting needles. A quandary always exists concerning the amount of tissue required for a specific diagnosis, relative to the size of the needle being used. Although the larger needle cuts a large surface area within the liver, multiple needle passes increases the probability of randomly striking a small blood vessel. As noted in the complication section, the relative risk of taking multiple samples versus a single large sample has yet to be determined.

The same criteria and considerations are used for selection of the entrance site, trajectory, and target as were noted with the aspiration needle, except for some differences with target selection. When the abnormality is quite small, it is best to plan the procedure so that the entire width of the abnormality will be sampled. When the lesion is large, it is best to choose a target so that a small portion of the normal liver as well as the abnormality are sampled (Fig. 61-68).

If one uses a cutting needle, it is reasonable to perform a small-needle aspiration before the cutting-needle biopsy. Using the small needle first is valuable for several reasons. By performing the biopsy first with a small needle, the operator and the patient can practice the procedure and determine the cooperation of patient and sufficiency of the local anesthetic. If the procedure goes well, the large-needle biopsy may proceed. If the procedure entails problems, adjustments can be made in regard to entrance site, target, trajectory, sedation, and local anesthetic.

Automated Biopsies

Automated biopsies have become popular because they minimize technical inconsistencies from one procedure to the next. A recent survey by Mayoral and Lewis,²⁶⁶ re-

vealed that almost 90% of radiologists use an automated cutting device for liver biopsy. The choice of such a device is subject to personal preference, but the smaller spring-loaded devices are easier to use and are reliable.

There are two substantive benefits of the automated gun relative to body size and the physical nature of a tumor. When a patient is quite large and the lesion is somewhat deep, it is difficult to move the outer cutting cannula of the manual Tru-Cut effectively because of the “drag” put on the cannula. Considerable resistance and “drag” on the cannula that make the manual device difficult to use also occur when the abnormality being sampled is quite fibrotic or hard.

Regarding technique, also note that with the movement of the needle, “recoil” occurs. One of our colleagues has

Figure 61-68. Scan shows biopsy of mass in left lobe, with cutting needle trajectory planned to cross the normal liver. This provides a protective cuff to minimize bleeding or tearing of tumor surface. A trajectory directly into the left lobe was avoided.

shown than if one holds such a device firmly rather than loosely with one hand, there is an improvement in sample size by about 14%.

Additional Caveat

When sampling an abnormality in the upper liver, there are several factors to consider in avoiding the pleura and the diaphragm. First, the normal diaphragm is much higher anteriorly than posteriorly; thus, a lateral approach is safer than a posterior one, and an anterior one is safer than a lateral one. As long as one does not see aerated lung, a pneumothorax will not occur during liver biopsy. Ample local anesthesia is critical to avoid undue patient discomfort and movement of the diaphragm, which might cause a complication during insertion of the needle.

One group has provided their experience with transdiaphragmatic biopsies. It is my opinion that although this may be true for small-caliber needles and reportedly is safe in their experience, the concept "flies in the face of common sense." Widespread application of this method will surely have a higher incidence of complications. If it is ever used, it surely would involve only small-caliber aspiration needles.

Factors Affecting Accuracy

One of the most important factors to consider when evaluating the outcome of various techniques is the extent of disease present at the time of the biopsy. The greater the number and the larger the lesions within the liver, the greater the probability of a positive biopsy. Conn et al⁵⁷ studied this with a series of blind biopsies performed on cadaver livers at autopsy. They graded the degree of involvement of the liver by the number of lesions and found the following recovery accuracy. Grade I, 1 to 3 lesions had a 16% success rate; Grade II, 4 to 25 lesions had a 27% success rate; Grade III, 25 to 50 lesions had a 45% success rate; and Grade IV, with over 50% involvement by weight had a 86% success rate. This finding is important to consider whenever a new method, technique, or type of needle is first being reported in the literature.

It is quite clear that historically, guided biopsy procedures are superior to blind or unguided biopsy procedures. One of the first articles in diagnostic aspiration by Lundquist²⁵⁵ reported a high success rate in about 70% of cases using only manual palpation of the abdomen. In his series, the only cases sampled were those involving palpable nodules that would correspond to the Grade IV types of lesions as noted earlier.

Rasmussen et al¹³⁶ reported the first series on ultrasound biopsy using a 22-gauge needle with multiple passes. They recovered positive tissue in 70% of cases with ultrasound guidance, compared with an anticipated rate of 23% for blind biopsies (extrapolating Conn's⁵⁷ classification of his cases as described in the report). Subsequent reports showed similar results with success rates varying between 66% and 94%. Despite the advantages of the small needle, authors such as Ho noted the disadvantages of the aspiration types of biopsy:

Based on our study and the literature, the information obtained by fine-needle aspiration on the general state of the liver is not as comprehensive as from a tissue sample taken by the Menghini technique.

These data clearly indicate that several simple and obvious factors affect the results: (1) the appropriate technique must be used with each needle (see the earlier sections on methods of biopsy for both aspiration and cutting needles) and (2) diagnostic yield depends on accurate localization of the instrument. Meticulous placement of the device is critical regardless of the guidance modality used. As technology evolves and devices change, operator preferences may change as well. The effect of needle size on diagnostic success has been well documented for aspiration needles in both in vitro and in vivo studies. Andriole et al¹⁰ studied the yield in liver biopsy of various aspiration needles and found that in vitro there was a definite increase in the diagnostic material with the larger-caliber needles. In a series of liver biopsies Pagani et al^{316,317} reported the results of using both 18-gauge and 22-gauge needles. They found a significant benefit 85% versus 98%, respectively, without any difference in the complication rate. In our own institution the diagnostic yield and complication rates of various aspiration needles have been determined and compared with cutting needles; these rates were reported by Martino et al²⁶⁵ and Ha et al.¹³⁶ With a single pass with aspiration needles and providing samples for both slide smears and cell block material, the diagnostic yield for malignant disease with a 22-gauge needle was 60.9%, compared with the 20-gauge needle at 77.6%. It is important to note that Pagani's data were based on the performance of multiple passes, and that our data involved single passes, which explains their higher yields.

From these data and those of Ferrucci et al^{88,89} it is clear that the more needle passes taken, the higher the diagnostic accuracy. In their series they selected 20 cases that were positive and looked at the diagnostic yield for each needle pass. The yield was 75% with one pass and 90% with two passes. (One can never expect 100% yield even with five passes.) In the same article, Ferrucci's overall yield was 82%. Even with blind biopsies the diagnostic yield increases appreciably with multiple passes. Grossman et al¹³⁰ noted an increase in the diagnostic yield from 41% to 54% with two passes and Conn and Yesner⁵⁷ noted that the yield increased from 47% to 58% with two passes.

All of the comparison articles concerning diagnostic yield from aspiration and cutting needles (single passes) have shown that cutting needles are superior to aspiration needles. The two comparison articles using a single pass were reported by our group. Martino et al²⁶⁵ showed that the diagnostic yield of Menghini and Tru-Cut biopsy needles was 88.1%, compared with 60.9% for 22-gauge aspiration needles. Our more recent experience reported by Ha et al¹³⁶ showed the 14-gauge Tru-Cut needle to be superior to the 20-gauge aspiration needle, with yields of 90.2% as compared with 77.6%. A comparison article by Jacobsen et al¹⁹⁰ showed a slightly greater accuracy with a skinny needle; however, their comparison was flawed by the fact that they took three passes with the skinny needle and only one with the cutting needle.

For benign disease, all reporting authors have shown a clear advantage for the cutting types of needles relative to

determining specific disease processes. In our most recent experience reported by Ha et al,¹³⁶ the cutting needles provided a specific diagnosis in 88.5% compared to 39.4% for aspiration needles; nonspecific diagnosis was provided in 11.5% by the cutting and 48.8% for the aspiration needle.

The combination of slide smears and histology can provide an added increment of positivity for the results. Numerous authors, including ourselves, attest to the benefit of combining aspirate samples with cell block histology. In our most recent study, the addition of cell block histology increased our diagnostic yield from 54.8% to 77.4%. Other authors including Sherlock et al,³⁵³ Grossman et al,^{129,130} Carney et al,⁴⁶ and Atterbury et al¹² have noted that producing a cellular smear by "rolling" the sample on a slide adds some additional accuracy. These authors showed an increase in positivity of between 3% and 17% by performing this technique. The only plausible explanation for this result is that the needle passes through the tumor during its incursion but no tissue is "cut." The cells are located in the side of the tissue core and can therefore be "smeared" onto the slide.

The automated cutting needles have added a new dimension to procedures. Prior to their introduction, cutting needles were seldom used for biopsies. In a recent survey, more than 90% of radiologists performing liver biopsies use the automated devices. Strangely enough, Hopper et al¹⁸⁰ in the evaluation of numerous automated devices, noted that the gold standard device to which all devices should be compared and the one as yet unsurpassed is the 14-gauge manual Tru-Cut device.

The success of percutaneous liver biopsy by CT guidance depends on the various important factors noted earlier. In our experience, the success rate for malignancy and benign disease has varied according to the type of needle used and the abnormality being sought. The success rate for sampling all malignant disease with aspiration needles is 77.6% and for cutting needles, 90.2%. The success rate for benign disease is 39.4% with aspiration needles and 88.5% for cutting needles.

Complications

As experience with guided biopsy procedures has accumulated, the same types and spectrum of complications have occurred with guided biopsies as have occurred with unguided procedures. These include biliary peritonitis, tumor seeding,³¹¹ hepatic infarction, pneumothorax, inadvertent puncture of bowel, abscess, and hemorrhage.⁴¹⁶

In regard to complications, the logical differences between aspiration and cutting needles must be made clear. In view of the wide variety of devices used and reported, some general as well as specific comments should be made.

From our experience there is little question that there is a slight difference in complication rate between the cutting needles and the aspiration needles. It is also true with experience and refinement of techniques that there can be improvement in these rates. In reporting our various series, we have shown a decrease in the complication rate with minimal improvements as we have refined our techniques. In our second report in reference to aspiration needles,

Martino et al²⁶⁵ reported a complication rate of 0.83% for serious complications, and in our most recent study by Ha et al¹³⁶ we reported a complication rate of 0%. Relative to cutting needles, Martino et al²⁶⁵ reported a complication rate of 1.44% and in our recent report by Ha et al,¹³⁶ the complication rate was 1.1%. In our most recent assessment of complications, the complication rate for cutting needles was 0.5% in 200 cases. Our experience indicates that complication rates can be quite low and acceptable for all needles if appropriate techniques are used.

The more obvious factors that affect complications include coagulation status, lesion characteristics, characteristics of the needle, and the number of needle passes.^{379,416} The presence of ascites is not a contraindication for biopsy of the liver. A review of our cases and several reports by other authors confirm this. Bernadino et al²⁷ and Little et al²⁴³ showed that ascites had no impact on complications. Furthermore, from a common-sense perspective, one can understand this quite easily. If one assumes that local pressure on a biopsy site might tamponade bleeding, the presence of intraperitoneal fluid actually increases intra-abdominal pressure and surely would not have an adverse effect on hemostasis. If there is any relationship, it would be because the most common cause of ascites is cirrhosis, which can be associated with compromise of coagulation factors. Hence, if coagulation studies are normal, ascites should be irrelevant.

Coagulation Status

One obvious factor that affects complications is the coagulation status of the patient. For biopsy using either an aspiration or cutting type of needle, we prefer to have the platelet count greater than 50,000, the INR less than 1.2, and the prothrombin time less than 14 seconds. If either value is not within the desired range, corrective action should be taken as needed (either platelet transfusion or administration of fresh frozen plasma). (See the general section on coagulopathy under general preprocedural items for new method to correct coagulopathy.) Patients should also not be on any anticoagulating drugs such as aspirin or warfarin (see section on contraindications). Unusual problems such as hemophilia, Christmas disease, lupus, or renal failure must be addressed individually. If there is any question of an unusual coagulation status, a bleeding time should be measured. This is the most accurate method of determining bleeding status because it is an *in vivo* test that takes into account all factors including the coagulation factor cascade, capillary fragility, and platelet function. An abnormal bleeding test warrants a consultation with the hematologist to preclude any major problems.

Lesion Vascularity

The other factor that is seldom discussed and is actually quite important is the vascular nature of the abnormality being biopsied. We have encountered bleeding problems in patients with vascular lesions such as hemangiomas and metastatic renal carcinoma. Several others have reported serious problems with vascular bleeding. Bret et al^{37,38} reported a small series of hepatomas biopsied using a 22-gauge needle for aspiration and some serious hemorrhagic complications. One of the patients required transfusion,

Figure 61-69. Significant hemorrhage can occur as a result of numerous factors. This scan shows a large hematoma outlining the capsule of the liver in the lower portion of the abdomen caused by a single pass of a 20-gauge Chiba needle (performed by the author). The patient has diffuse metastatic renal cell carcinoma to the liver that was very vascular.

two required corrective surgery, and one died. Considering the small caliber of the needle and the experience level of the authors, the only explanation for these problems is that hepatomas and other tumors that are inherently vascular are predisposed to bleeding (Fig. 61-69).

There is also a case report of a bleeding death from a 22-gauge needle biopsy of a cavernous hemangioma. The authors did not mention assessment of vascularity using a dynamic study, nor did they choose a trajectory through a small cuff of normal liver.

Smith et al³⁶⁰ also reported that one cannot prevent complications by using a fine needle. From a mail survey they determined that in a series of 63,000 reported cases there were 27 cases of significant hemorrhage requiring transfusion, and 3 deaths.

Needle Traits

Regarding the needles used in cases of reported complications, several points must be made. First, as stated, there is a difference in the overall complication rate between cutting needles and aspiration needles. Second, there is no definite difference in the complication rates among the various caliber needles of the aspiration type. Pagani et al³¹⁶ reported no difference in the complication rate between 18-gauge and 22-gauge needles. In our two sequential series, our complication rates actually dropped when we switched from a 22-gauge to a 20-gauge needle. One cannot necessarily infer that the reduction in the rate was due to the needles; the reduced rate is most likely a result of experience and technique that naturally overcomes any minimal difference among the aspiration needles. In a laboratory study on animals by our group (see Table 61-2), there were only minimal differences among any of the needles less than 18 gauge, but there was significant difference between these and the larger-gauge needle.

Different Calibers of Cutting Needles

The key question recently answered is the relative risk of bleeding among the various Tru-Cut types of needles of

Table 61-5. Blood Loss and Amount of DNA after Biopsy

A: Blood Loss

Needle Size	No. of Samples	Unadjusted Blood Loss (g)*
14 gauge	64	1.69 (2.22)
18 gauge	63	0.74 (0.89)
20 gauge	63	0.32 (0.50)

B: Amount of DNA

Needle Size	No. of Samples	Amount of DNA per Sample (μg)*
14 gauge	17	40.38 (10.29)
18 gauge	16	12.18 (3.84)
20 gauge	16	5.86 (1.58)

* Data are means. Numbers in parentheses are 1 SD.

different calibers. A recent laboratory study by Plecha et al compared the amount of diagnostic tissue obtained to amount of local bleeding with various calibers of Tru-Cut needles (Tables 61-5 and 61-6).^{328a} They found that per unit of tissue, there was slightly more bleeding with the larger needle (14-gauge) as compared with the 20-gauge needle. The data further showed, however, that if one looks at the relative tissue yield (reflected by the quantity of DNA) compared to the blood loss, there is relatively no difference among the various caliber of needles (20, 18, and 14 gauge). In theory, if one was required to obtain a finite amount of tissue, the efficiency and risk of using a 14-gauge needle may well be theoretically less. As noted earlier, the amount of bleeding per unit of diagnostic tissue is no different among the needles. The second factor to recall is that significant bleeding is usually the result of inadvertently striking a small artery. This is essentially a random event so that if multiple passes with a small-caliber needle are required, there is a statistically greater chance of bleeding. It may be that three to four passes with a 20-gauge needle are less safe than one pass with a 14-gauge needle. That is, it has not been clinically determined whether multiple small-caliber Tru-Cut needles

Table 61-6. Statistical Results for Each Outcome Measure

Comparison	Blood Loss	Blood Loss with Amount of DNA per Sample	Blood Loss with Needle Chamber Volume	Blood Loss with Amount of DNA per Sample and with Needle Chamber Volume
14 vs. 18 gauge	.025*	.24	.14	.0002†
18 vs. 20 gauge	.059	.76	.42	.025*
14 vs. 20 gauge	<.001†	.47	.07	.0007†

Note: Data are *P* values. Blood loss was measured in grams. Amount of DNA per sample was measured in micrograms. Needle chamber volume was measured in cubic millimeters.

* Difference was statistically significant ($P < .05$).

† Difference was statistically significant ($P < .001$).

are safer to use than a single pass with a large needle. In our practice we have actually had a major complication with the use of a 20-gauge Tru-Cut, which resulted in a major hemorrhage and required a surgical procedure.

Needle Passes

Although multiple needle passes increase the diagnostic outcome, they introduce a higher incidence of complication with all needles, including small aspiration types. In our experience we limit our needle passes to two in virtually all cases. The expected yield should be about 75% to 85%. If the procedure is not a successful one, a repeat two-pass biopsy is warranted, after which one should choose either a cutting needle or a surgical procedure. The adverse effect of numerous needle passes was best documented in a survey by Smith.³⁶⁰ We concur with his opinion that the number of needle passes even with a small needle should be limited to as few as possible. As is seen in reports in the literature, serious complications occurred in cases involving four or five needle passes, and none occurred in those involving two or less passes.

Coagulopathy

Patients with coagulopathy should have the appropriate treatment as indicated to improve coagulation. Patients with low platelet count should receive several units of platelets. Considering the time delays required with laboratory studies and the life expectancy of platelets, I manage the administration as follows. If I intend to give six units of platelets, I will send a blood sample for platelet count after the first two units; if the observed effect in the repeat count is what I anticipate as compared with the baseline value, I will then proceed with the procedure immediately following the fourth unit. The last two units are given after the biopsy. The same type of laboratory and administration schedule is used with fresh frozen plasma for an elevated prothrombin time. Patients requiring factor VIII are treated in a more routine fashion.

Patients with impaired platelet function on the basis of either medication such as aspirin or renal failure can be handled in the following manner. Although the effects of aspirin are long-lasting, I consider a passage of 7 days after the last aspirin an acceptable period after which the biopsy can be performed. For renal failure patients, one can administer DDAVP in appropriate doses to lessen the complication risk for biopsies.

If the coagulation state cannot be returned to normal, one should use special hemostatic techniques as described earlier under coagulopathy and later under high-risk procedures. These have been proved effective for the prevention of bleeding.

Special Pathologic Entities

Hemangiomas. Although cavernous hemangioma is said to be the most common hepatic tumor, it has received little attention until recently because it is benign and seldom causes spontaneous problems. Attention has focused on these benign masses in recent years because as imaging technology has become more refined, commonly detected lesions can be mistaken for more serious problems. Correct diagnosis is important to prevent unnecessary surgery and

errors in cancer staging. If inappropriate imaging studies are performed or incorrectly interpreted, a patient may present for a biopsy procedure (see the chapter on liver diagnosis for details).

In most instances, hemangiomas typical on imaging will be correctly diagnosed but occasionally an atypical one will present for biopsy. Surprisingly, once the typical vascular hemangiomas are excluded there is little risk of a significant complication from the atypical variety. The reason for this is that the pathologic features that make their imaging appearance atypical also preclude the potential for bleeding complication. Stated differently, the increased vascularity of hemangiomas is what gives the typical appearance on such imaging modalities as CT enhancement, isotope pooling, etc. When the increased vascularity is not present because of thrombosis, fibrosis, or hyalinization, the lesion is unlikely to bleed with a biopsy.

Clinically the reported experience has supported this concept.³⁵⁶ As we have noted in our previous editions, the only complication we have had with hemangiomas occurred before the development of bolus dynamic scanning. Since the appropriate use of contrast material, we have had no problems with hemangiomas. We have inadvertently biopsied numerous atypical hemangiomas with 14-gauge cutting needles under the assumption that they were lesions other than hemangiomas. Other authors including Spamer et al,³⁶⁷ Cronan et al,⁶² and Solbiatic et al,³⁶² have reported the safe biopsy of atypical hemangiomas. These authors have also noted the difficulty in diagnosing hemangiomas with small aspiration needles; they note also that hemangiomas can inconsistently be diagnosed with special-purpose needles and consistently diagnosed with the standard cutting needles.

Cirrhosis. The issues surrounding the biopsy of cirrhotic livers are only two, one concerning the possibility of complications and the other concerning intactness of tissue samples. The cirrhosis itself does not predispose to problems, but associated changes may. One must always be aware of possible prothrombin elevations and the pathologic changes of cirrhosis, which increases the hepatic concentration of small arteries and venous collaterals. We have experienced a case of life-threatening hemorrhage in such a patient, reported by Nachamoto et al.²⁹⁹ If one chooses a needle to sample cirrhosis, the side-cutting Tru-Cut needle has been shown to be better than the Menghini type of needle in preventing fragmentation of a fibrotic, cirrhotic liver sample.

Fatty Metamorphosis. Since the introduction of CT scanning, it has become apparent that fatty change can be quite focal and can perfectly simulate a neoplastic lesion. Although many times the geographic appearance will betray its true identity, biopsy of such lesions is quite common. A cutting type of needle is superior to aspiration types for diagnosing this entity.

Cystic Abnormalities. With these abnormalities, one important point should be made. The fluid obtained from such lesions may not be diagnostic and one should always endeavor to sample the wall of such lesions. If one is using an aspiration needle, one should send two samples as

follows. The first sample of fluid should be aspirated and sent for cytology. A second cellular sample should be obtained from the opposite wall of the cyst by "reciprocating" the needle against the opposite wall.

Endocrine Tumors. Biopsy of nonfunctional⁹ endocrine tumors is straightforward. When functional tumors are to be biopsied, one should be both cautious and prepared to treat any symptoms if a hormone release occurs. It is important to note that a death has been reported after biopsy of metastatic carcinoid in the liver.³² Generally, biopsy of functional tumors is discouraged.

Echinococcus. Several series of percutaneous treatment of *Echinococcus* are reported in the literature. While it is true that anaphylaxis is not as likely as previously thought, percutaneous puncture for diagnosis is discouraged because the imaging appearance of daughter cysts is characteristic and a serum test can accurately confirm the diagnosis. The major concern in such patients is to prevent spillage of daughter cysts into the peritoneum or other spaces. If therapy is considered, special precautions should be taken; those are discussed under the therapeutic section.

Hepatoma. Primary tumors warrant a separate discussion because they have some unique traits from several perspectives.³⁷⁶ Clinically, the specific nature can usually be suspected by an elevation of the serum alpha-fetoprotein level. Differentiation from other entities may be difficult from an imaging perspective; recent data, however, suggests that MRI can differentiate between regenerating nodules and hepatomas. Hepatomas tend to have a higher T2 intensity than do regenerating nodules. If such a lesion were only visible on MRI, it would be appropriate to perform an MRI-guided procedure.

Biopsy of hepatomas has variable results, depending on the technique used. Successful diagnosis may be difficult with small needles because differentiating normal hepatocytes from well-differentiated tumors can be difficult with small aspiration samples. This problem can be overcome by taking numerous aspiration samples or by using a larger needle. The trade-off is in the form of a potentially higher complication rate. It is well-documented that hepatomas have an increased vascularity and therefore predispose to a higher complication rate. Wittenberg et al⁴⁰⁶ reported a significant bleed requiring a two-unit transfusion after skinny-needle aspiration of a hepatoma. More recently Bret et al³⁸ reported successful diagnosis in 63 of 69 hepatomas with a 22-gauge needle and multiple passes, but numerous complications resulted. In their series they had four major complications in the 69 patients; these consisted of one death and three hemorrhages, two treated by surgery and one by transfusion alone.

Complications reported by other authors have included the full gamut of problems, including infarction, infection, and tumor seeding within the needle tract. With the ubiquitous use of procedures numerous cases of tumor implants have occurred with hepatomas. This can be avoided by use of a coaxial method. The outer cannula prevented implantation of cells.

Pancreas

Percutaneous procedures of the pancreas have become widely accepted as the method of choice for the diagnosis

of various pancreatic problems. In major medical institutions it is routine practice for a percutaneous aspiration procedure to be used in lieu of exploratory laparotomy for diagnosis and treatment of tumors and inflammatory processes.*

Tumor Indications

The indications for using percutaneous procedures for pancreas are quite broad and relate to diagnosis of tumors, pseudocysts, or infectious processes. Relative to the diagnosis of tumors, I believe the threshold for biopsying any mass is quite low because of both the high success rate and the low incidence of significant complications. Any suspected solid tumors of the pancreas should be biopsied very early in the course of patient treatment for two reasons. For those patients with large inoperable tumors, a biopsy should be performed at the earliest time to make the definitive diagnosis and to eliminate the need for more expensive or complicated procedure such as surgery or endoscopic procedures. For subtle cases, this offers the best opportunity for early diagnosis and surgical treatment.

Indications for Cystic Tumors

The indications for sampling cystic tumors are somewhat different than other problems. With these tumors there are really two objectives. The first one is to differentiate cystic tumors from pseudocysts of the pancreas. By imaging alone, it is virtually impossible to distinguish between a pseudocyst and a cystic tumor. In such cases the goal is to aspirate fluid from a fluid-density mass so that an assay of amylase can be performed to diagnose a pseudocyst; very high levels are indicative of a pseudocyst. When the amylase content is low, one cannot distinguish between a cystic tumor and a "burned-out" pseudocyst. Such cases typically go to surgery for definitive treatment. The other purpose of aspirating such tumors is to distinguish among mucinous, mucinous cystadenocarcinoma, and serous cystadenomas. My personal experience with these is limited, so I must depend on the literature. The outcome with these lesions is not completely clear, as discussed later under pathologic results and accuracy.

Other Indications

In cases of severe inflammatory processes, CT-guided aspirations are indicated to obtain fluid for diagnosis of infected processes. The presence of infection is a critical determinant for overall outcome of severe pancreatitis, as noted in the pancreas chapter.

If one is careful, meticulous, and judicious in technique, one can even justify aspiration of unusual fusion anomalies of the gland if there is any question of tumor.

Contraindications

There are only a limited number of contraindications that are primarily related to the presence of vascularity

*References 25, 70, 73, 119, 144, 164, 175, 257.

and anatomic approach. In some rare circumstances, the vascularity of tumors will be so great or collateral vessels so numerous that no type of aspiration or biopsy procedure should be performed. The presence of a large pseudoaneurysm should also be a contraindication for a procedure (Fig. 61–70).

A relative contraindication is the presence of a large number of varices. When pancreatic tumor obstructs the splenic vein, many venous collaterals will be created. When there are a large number, one must decide if a clear anatomic pathway exists or not and thereby proceed or defer the procedure.

If patients are immunocompromised, fluid-density masses should not be aspirated while traversing bowel; if no pathway is available, such procedures should be avoided.

Needle Selection and Technique

Sampling of the pancreas can be performed by either aspiration or cutting needles. In most cases, a 20-gauge aspiration needle is appropriate to obtain a cytologic specimen. The diagnostic yield is typically quite good and there is a low incidence.

In certain circumstances one can perform biopsy of the pancreas with a cutting needle as large as 18 gauge. The key to success with these devices is to carefully target the pathologic areas of the gland so that when a biopsy is taken, there is minimal trauma to the functioning glandular tissue. Elvin et al⁵² reported a series of 47 patients in which cutting needles were successful. Cutting needles have also been used successfully for biopsy also of pancreatic transplants by Aideyan et al⁴ with few complications.

Complications occur when an uninvolved structure such as a vessel, pseudoaneurysm, or functioning glandular tissue is damaged (see later section). Such complications have been reported with both small-caliber aspiration and cutting needles.

General Technique and Anatomic Approach

The choice of imaging technique for diagnosing and localizing pancreatic masses is important. A good contrast-enhanced study is critical for several reasons in planning a biopsy procedure. The success of the biopsy depends on accurate localization of the tumor and display of the vascularity of the area. If a tumor is avascular, then the margins of the tumor can be defined more clearly and accurately targeted for the aspiration needle. Although one group has noted that many pancreatic tumors are diffuse, it has been our experience that well-defined margins can usually be found if careful technique is used.

If the pancreatic tumor is an unusual one with increased vascularity, the enhanced vascularity can be noted and advisability of the procedure can be reconsidered or the planning simplified. Hypervascular tumors include non-functioning islet cell tumors, islet cell tumors, and certain metastatic lesions such as renal cell carcinoma (see Fig. 61–69).

Figure 61–70. These images (A to C) demonstrate the importance of performing a dynamic bolus injection study for every pancreas biopsy. A, This image shows what appears to be a large mass in the body of the pancreas with no indication of any prior history. Biopsy was planned. There was a prior history of contrast allergy, so no contrast study was available. B, At the time the patient was on the table, a bolus injection was performed. Note the very large enhancing pseudoaneurysm (A). C, Angiogram was performed in the course of embolizing the aneurysm (A). Note the origin is from the splenic artery (S).

Figure 61-71. Biopsy of the pancreas performed from an anterior approach. The needle is positioned in the low-density area (arrows) of the tumor. Note the trajectory was planned to avoid the superior mesenteric vein and smaller veins, (curved arrows).

The proper vascular enhancement can also demonstrate any collateral vessel formation or vascular abnormalities that can produce a multitude of small and large venous and arterial collaterals, all of which should be avoided. The most common entities creating confusion include pseudoaneurysms, varices, and cavernous transformation of the portal vein (see pancreas chapter).

When planning the trajectory, I choose the target in the pancreas that is well-defined but does not appear necrotic. If the anatomy is optimal and one's experience is extensive, all structures should be avoided, except the fat of the mesentery and the pancreas. If anatomy is less than optimal or one is less experienced with angled procedures, then penetration of certain structures can be tolerated (Figs. 61-71 to 61-73).

If one considers penetrating a loop of colon, possible adverse outcomes should be considered, and careful judgment should be exercised. It is my judgment that penetra-

Figure 61-72. Posterior approach for biopsy of low-density tumor of pancreas. The mass proved to be a neuroendocrine tumor, with no clinical function noted. Posterior approaches are satisfactory, but one must be careful to avoid pertinent structures and vessels; penetration of vessels is not advisable because long-term complications are likely to occur. The small series reported are not valid in recommending a transvascular approach routinely.

tion of colon should be avoided in all cases because it contains many pathogenic organisms. Avoiding loops of bowel is a good thing to do if at all possible because although it is commonly done, there is always a finite probability of leakage. We at least make an attempt to plan a pathway that avoids such loops using several techniques. First, one plans the trajectory accordingly, and then can use several maneuvers to accomplish this (Fig. 61-74).

Certain anatomic structures I absolutely avoid, but others I will accept the possibility of traversing during an aspiration procedure. I definitely prefer to avoid traversing any major artery or vein, as well as the spleen, to preclude the risk of bleeding. I accept penetration of the stomach or liver if it is absolutely necessary, in the belief that the risk is minimal (Fig. 61-75).

Small bowel can be penetrated safely if a necrotic tumor or cyst is present and the tumor mass is not cystic. I think avoidance is important for two reasons. In our studies we have confirmed that a small inoculum of bacteria can be carried from the bowel by a skinny needle. If that inoculum is carried into a solid tumor or structure, there is little possibility for bacterial growth. If it is carried into a fluid collection, however, the body's immune system has difficulty in eliminating the inoculum. The fluid space acts as a culture medium in which, at the time of contamination, the phagocytes' and antibodies' functions are impaired (Fig. 61-76).

In the immunocompromised patient, the avoidance of all bowel is important because with the severe compromise produced by chemotherapy, transplant treatment, or chronic conditions, even the smallest inoculum of virulent pathogens can create a serious problem. The nature of the bacterial contents can vary in disease states, especially those associated with abnormal or altered peristalsis. The amount and type of various bacteria depend partially on the enteric peristalsis. As an obstruction occurs, there can be ascent of the colon flora retrograde into the small bowel and stomach so that the flora in those viscera may include many gram-negative species. Although some authors have implied or stated that concerns about secondary infections are excessive, there are several reports of serious complications from such infections.

Another precaution to be taken is avoiding possible penetration of a dilated bile or pancreatic duct. Damage to these structures could result in leakage, peritonitis, or fistula formation.

Although it is true that one could probably penetrate any and all structures routinely and not have a problem for a long time, most likely the statistical probabilities will catch up with the interventionists if too many cases are performed with disregard for potential problems. One must remember the numerous case reports of complications and deaths following percutaneous pancreatic instrumentation.

Recently an approach has been proposed for pancreatic tumors that I consider inappropriate until further data are accumulated. Gupta et al¹³⁵ reported a small series of patients in which they intentionally traversed the vena cava from a posterior approach. I fully support making a posterior approach in some patients when no other clear access is available, but I think it is appropriate to try to avoid major vessels such as the aorta or vena cava. If during those attempts one inadvertently traverses either of those

Figure 61-73. A, Dynamic bolus scan shows a low-density mass in the pancreas. The superior mesenteric artery (*horizontal arrow*) and superior mesenteric vein (*vertical arrow*) are noted. The patient was positioned in the lateral position to move the "bowel" out of the way. B, Initial approach shows a loop of small bowel (*arrow*) intervening in the pathway; also, the direction is such that the needle might strike the superior mesenteric artery (*arrow*). Tumor (T) is noted. C, Readjustment of the needle is made so the needle is directed toward the mass and partially compressing loop of small bowel. By turning the needle so the bowel is caudad toward the bowel and pushing slowly, the needle can be pushed aside by peristalsis. D, Final image shows placement of the needle in the pancreatic mass.

vessels, then it is comforting to know that a bad result is unlikely. There is no question that if this method is adopted, more complications will result.

New Methods for Cutting Needles

Since the last edition, the usage of cutting needles has grown remarkably. With the increased usage, refinement of techniques, and improvement of imaging equipment, these

needles have now become used commonly even in the pancreas.

To effectively and safely use these needles, several basic tenets must be followed. Every case should have a high-quality vascular study with CT bolus. In many cases, a good vascular study will have been performed during the routine diagnostic examination. In such cases one can quite

Figure 61-74. Guided aspirations of pancreatic pseudocysts are critical to the differentiation from cystic tumors. This scan shows aspiration of a small cystic mass adjacent to but behind the pancreas. Because of the high amylase content, the concern about a cystic tumor was eliminated.

Figure 61-75. A large mass (*arrows*) in the body of the pancreas extends into the submucosa of the stomach. A transgastric approach was used to sample the mass.

Figure 61-76. Avoidance of colon is very important if at all possible, because of high bacterial count in colon. *A*, The approach used was to insert the needle from a lower origin, to traverse below the transverse colon. At this level, the needle is pushing by the lower edge of the colon and is directed cephalad. *B*, Slightly higher scan shows the needle entering the pancreatic mass. Such attempts are worthwhile, and occasionally one may penetrate the bowel. At least over a long experience, the probability of a complication is less likely the fewer penetrations are made.

clearly see the normal vessels, collateral vessels, and any tumor vascularity. Avoidance of these vascular structures is absolutely critical to prevent bleeding. Furthermore, clear delineation of the target structure is critical to careful positioning of the gap into the mass (Fig. 61-77). One must avoid cutting a hole in normal-functioning parenchyma and also any ductal structures. Damaging the normal parenchyma may result in severe pancreatitis. Damaging the ductal system may result in bile peritonitis or pancreatic ascites.

Implications for Surgery

In recent years, our surgical colleagues have become more aggressive in approaching the resection of pancreatic cancer, because new imaging methods can better define anatomy and screen patients for surgery. Several recurring questions are raised that can be answered by reviewing certain reports. First, the accuracy of percutaneous image-guided procedures was shown by Savarino et al³⁵⁰ to be equivalent to those biopsies performed during laparotomy.

Another common question raised is whether or not percutaneous biopsy "seeds" the peritoneum and thereby affects the ultimate outcome. Johnson et al¹⁹⁶ confirmed two important principles. These authors studied the presence of

tumor cells in the peritoneum at the time of laparotomy in two groups of patients. They found viable tumor cells in both groups, biopsied and nonbiopsied, with no statistical difference between the two groups. Second, they found the ultimate survival was no different between the groups. Balen et al¹⁵ also confirmed that biopsy produced no adverse effect on the survival of patients.

Accuracy of Various Tumor Diagnoses

Many articles have now appeared about the accuracy for diagnosing pancreatic tumors. It is generally accepted that the larger the needles, the better the accuracy. In our series by Dickey et al⁴⁸ we showed the benefit of using 20-gauge rather than 22-gauge aspiration needles for diagnosing typical adenocarcinoma.

With aspiration biopsies virtually every tumor type has been successfully diagnosed using modern cytopathologic methods. Iselin et al¹⁸⁷ reported a small series in which cytology was able to distinguish mucinous and serous tumors. Gupta and al Ansare¹³³ reported success in diagnosing four cases of mucinous cystadenoma of the pancreas. Acinar tumors diagnosed by aspiration were reported by Samuel and Frierson.³⁴⁵ Papillary tumor was diagnosed by Suarez et al³⁷³ and Mandrekar et al.²⁶¹ Islet cell tumors can be diagnosed by cytology according to Collins and Cramer.⁵⁶ As noted later under specific entities, I am still of the opinion that one should not biopsy functioning tumors because an endocrine release and possible hormonal crisis may result.

Complications

Although most authors infer that percutaneous pancreatic biopsy is without risk, a number of mild complications and a number of serious complications have been reported. The mild complications reported by Smith,³⁶⁰ Goldman,¹¹⁸ and McLoughlin²⁷¹ included transient rectal or colonic bleeding, probably because of trauma to the transverse colon. Ohto³⁰⁹ reported one case of transient hematemesis following a biopsy. Other mild complications also included four cases of mild pancreatitis that resolved; these were reported by Evans and McLoughlin.²⁷¹

Figure 61-77. A large mass (M) in the pancreas was believed to be lymphoma. A cutting needle sample revealed lymphoma.

The serious complications related to tumor sampling (pseudocysts are reported later) have included hemorrhage, fatal pancreatitis,^{82,296} sepsis, cholangitis, fistula, and needle-tract seeding. Fataar^{85, 86} reported two cases of hemorrhage, one that required cardiopulmonary resuscitation and two units of blood, and one that resulted in a 6.5-cm hematoma in the mesocolon. Evans et al⁸² and Levin et al²³⁸ have reported cases of fatal pancreatitis following ultrasonic biopsies. Phillips et al³²⁸ reported one case of cholangitis and pancreatic fistula, as well as severe vasovagal reaction. Ferrucci et al⁸⁹ had a case of cystadenoma of the pancreas that resulted in generalized sepsis. Two authors, Rashleigh-Belcher³³⁵ and Ferrucci,⁸⁸ reported separate cases of needle-tract seeding from pancreatic carcinoma.

Based on our experience and a review of the literature, it is my belief that risks are directly related to inaccurate targeting and the number of passes made with the needle. This premise has also been recently stated by Smith^{358,360} (see earlier general section on complications).

With our conservative method and techniques, such as trajectory, number of passes, etc. that minimize all possible risk factors, pancreatic biopsy is safe and effective. As a routine, the risks are minimal enough that percutaneous pancreatic biopsy is considered an outpatient procedure. In our reported experience with 96 biopsies, including patients with 40 neoplasms and other abnormalities,⁷³ we had only one patient who had a transient elevation of the amylase (without clinical pancreatitis). Since that time we have encountered one patient who developed an acute abdomen following aspiration of a pancreatic abscess; as a result, surgical exploration was required.

Other Important Points

When the results are cytologically positive for malignancy, the disposition is obvious. If the cytologic results are negative, I place importance on the texture of the gland felt during the needle aspiration. If the gland is "hard" or the mass is large, surgical biopsy is indicated. If the gland is "soft" during aspiration of a subtle mass, no further investigation is needed. Surprisingly, many times normal acinar cells can be recovered in such cases. One may consider performing a small-caliber cutting needle with a 20-gauge needle if clinical circumstances dictate this as a preference over surgical exploration.

It is our belief that biopsy of a functioning endocrine tumor should not be performed. The definition of "functioning" is made on clinical information about these patients that includes specific symptoms associated with the released hormone (see Chapter 29). One author reported the successful but uneventful biopsy of a pancreatic insulinoma.¹⁹¹ Experience with a single case, however, should not be accepted as establishing the principle of safety; further experience is required before endocrine tumor biopsy can be generally recommended.

Specific Entities

Adenocarcinoma is the most common entity biopsied. There is nothing unique about this tumor beyond what has

been discussed earlier. Meticulous evaluation, trajectory planning, and good aspiration technique should be used as described earlier.

Acinar cell carcinoma is a rare tumor, so it is doubtful there will ever be accumulation of any significant number of cases. As predicted in our last edition, it has now been demonstrated that diagnosis can be made by aspiration biopsy; several cases were reported by Samuel and Frierson.³⁴⁵

Cystic Tumors

As noted in the pancreas chapter, cystic tumors of the pancreas are unusual entities that include both a benign and a premalignant variety. Differentiation of these tumors by imaging is not possible; it would therefore be convenient if one could differentiate the two by needle aspiration. Because one of the tumors is reported to produce glycogen and the other does not, it would also seem convenient if one could stain for this material. Practically speaking, it has not been possible to accomplish this in our laboratory. Authors who have reported have appropriately noted that there may be considerable sampling error and that the recovery of benign cells from one component may not exclude malignancy in another region. Several authors (Iselin et al¹⁸⁷ and Gupta and al Ansare¹³³) report success in differentiating the mucinous/serous cystic tumors as well as diagnosing cystadenocarcinoma. Most authors agree that it is not the results of the aspiration but rather the demographics of the patient that provides the best predictors of outcome and the need for surgery.^{100,199,392}

Endocrine Tumors

The biopsy of endocrine tumors that are nonfunctional (and thus are obscure as to their nature) is appropriate, but biopsy of a functional lesion is not. Although there is a case report of a biopsy of a pancreatic insulinoma,³³⁰ I believe the biopsy is inappropriate because of the possibility of a hormonal release. Because some endocrine tumors do not secrete active hormone, this stipulation applies to only functioning tumors. Nonfunctioning endocrine tumors occasionally are diagnosed by cytologic sampling, after it has been performed under the presumptive diagnosis as a routine neoplasm.

Pseudocyst Aspiration

Aspiration of pseudocyst fluid or inflammatory fluid is important for the exclusion of cystic tumors (as noted earlier) or the diagnosis of an abscess. Laboratory analysis of fluid from a pseudocyst will show a high amylase content, while that of a cystic tumor will not (see Fig. 61-74). Aspiration of any suspicious fluid collection in patients with pancreatitis should be performed to exclude pyogenic infection. When such procedures are being performed, one should be sure bowel loops are not being traversed to exclude the possibility of contaminating a fluid collection or recovering spurious culture results. Good evidence for this cautionary approach was provided by Smith who collected 16 cases of generalized sepsis from a physician survey.³⁶⁰

Cavernous Transformation of Portal Vein

Interestingly, in some cases cavernous transformation of the portal vein may produce a mass that will be recommended for a biopsy. In most cases when the vascular channels are large, the portal cavernomas can be recognized with a bolus dynamic scan. If a cavernous transformation of the portal vein does not have large vascular channels or rapid flow, such masses may not enhance with a bolus dynamic scan. In such cases, if a biopsy is inadvertently performed in a patient, a complication is most unlikely because the vascular channels are very small. Unaware of their pathologic identity, I have biopsied three such cases without difficulty.

Retroperitoneum

CT procedures in the retroperitoneum prove valuable because even though ultrasound and fluoroscopy have been used in the past, CT provides the best visualization of pathosis and instruments in this area. Only CT can visualize precise location of tumors in relationship to the aorta and vena cava.^{76,121,218,322}

Indications

The indication for procedures within the retroperitoneum are similar to those for other areas, it is usually the presence of a mass in a patient suspected of having some type of a malignancy or an inflammatory process.

Instruments

As in the other organ systems, we use our general guidelines for the selection of instruments. For a mass in a patient with suspected metastatic malignancy, I use a 20-gauge aspiration needle for a cytologic sample (Figs. 61–78 and 61–79). For unknown or undiagnosed tumors or for

Figure 61–79. For all retroperitoneal biopsies, it is prudent to perform a dynamic bolus scan. This scan shows a mass in the hilum (arrow) of the right kidney; note the numerous small vessels around the mass (M). A small-needle aspiration biopsy might be possible, but in cases such as this when lymphoma is more likely, such samples are not helpful. Even though the risk of a problem is small, the probability of success is very low.

lymphomas we use the side-cutting Tru-Cut needle (Fig. 61–80) or automated Tru-Cut.

In most instances the Tru-Cut needle is the needle of choice because it provides the largest well-preserved sample. Also, this instrument is the most carefully controlled because the cutting gap can be well seen on the CT scan and the cutting action occurs only at the gap. There is no possibility of “overshoot” during the procedure such as may occur with the end-cutting Menghini type of needle.

Even the beginning interventionist can biopsy fairly large masses in the retroperitoneum with this needle. With experience, even very small lymph nodes immediately adjacent to the major vessels can be sampled if the proper technique and attention to detail are observed.

Anatomic Approach

The approach used is typically posterior, adjusted according to the location of the kidney, major vessels, colon, small bowel, and psoas muscle.

Figure 61–78. A, Scan shows a small mass (arrow) between the vena cava and aorta. After a bolus injection, the needle was inserted between the vessels for cytologic sampling. B, The accuracy of needle placement is so precise, one can even “thread” a needle between the vessels and sample structures (C) slightly anterior. When passing needles by such vessels, it is always important to have the bevel directed toward the vessel.

Figure 61–80. A, A patient with a mass (M) adjacent to the kidney. This is more posterior than noted in the prior case (Fig. 61–79), and the vessels are located anteriorly. B, Cutting needle biopsy provided definitive information for lymphoma.

The posterior approach for such procedures is obviously easier with the patient lying in a lateral, anterior oblique, or prone position. If an aspiration needle is used, an anterior or posterior approach can be taken, but if a cutting needle is used, a posterior approach is necessary.

Most lesions are in the periaortic region, and in such cases the anatomy should be carefully examined and the aorta and vena cava traced through the entire expanse of the abdomen. As with the other areas, the bolus injection is important to define the location of vessels and the presence of any tumor vascularity (see Figs. 61–79 to 61–81). Carefully note other vessels such as the renal pedicle, the

splenic vein, the left gonadal vein, and the inferior mesenteric vein (which runs in the left periaortic area). Also, note the location of the ureters on both sides after the administration of intravenous contrast material.

If the vena cava cannot be identified, perform an injection of the foot vein to get better opacification. If the gonadal, inferior mesenteric vein or the ureter is not seen because of the surrounding tumor, do not search for them. In such cases they are so encased and infiltrated with tumor that they are nonfunctional. In over 25 years I have never penetrated or cut any of these structures inadvertently when they were not seen.

Several specific areas warrant special mention. The areas that are difficult to biopsy safely are the retropancreatic region and the area of the aortic bifurcations. In these areas there are multiple vessels branching and converging that make exact delineation difficult. In these areas I usually perform only an aspiration biopsy to avoid the possibility of injuring one of the vessels.

Although the approaches noted here seem rather risky to the neophyte, it is quite clear that the average radiologist can develop sufficient skill with experience. Although I do not recommend several articles that report the safety of penetrating the aorta or vena cava during the course of a pancreatic procedure, one can appreciate that surely an inadvertent penetration while attempting these procedures is probably a low-risk situation. Again, I do not recommend traversing vessels, but one should surely develop the techniques to pass by such structures, knowing that a penetration would probably not be catastrophic.

Results

The biopsy of lymphoma was previously controversial but is no longer. Using a 14-gauge cutting needle, one can diagnose not only specific lymphomas successfully but unusual entities such as atypical *Mycobacterium*, retroperitoneal fibrosis (Fig. 61–82), and even sarcoidosis. If clinically indicated, one can get ample tissue for electron microscopy, gene studies, or chemical assays. Quinn et al³³⁴ reported a series of 43 cases in which cutting needles correctly diagnosed lymphoma in 84%. The authors recommended that image-guided biopsy be performed as a first procedure in all cases of suspected lymphoma.

Figure 61–81. A, Potential biopsy showed a large mass in the retroperitoneum on the left of the aorta. B, Scan with the patient on the right side was performed with bolus. The mass proved to be a large hematoma in a contained rupture of the aorta. No biopsy was done.

Figure 61-82. A, Scan shows a poorly defined mass around the aorta, enhanced by contrast medium. B, Scan during the biopsy shows a mass adjacent to the aorta, which proved to be retroperitoneal fibrosis. Tissue samples with a 14-gauge needle are ample enough to diagnose unusual processes.

Complications

Only limited data are available on the retroperitoneum.^{420,421} In our preliminary study comparing large and small needles, only one complication occurred.²¹⁸ A small asymptomatic hematoma appeared on the CT scan during the small-needle aspiration before the large-needle biopsy. The diagnostic accuracy was high for both metastatic disease and lymphoma. Bernardino et al²⁷ have also reported a good success rate for diagnosing lymphoma.

Kidney

Two types of CT biopsies are performed on the kidney, one for evaluation of masses and another for the sampling of diffuse parenchymal disease. In many instances CT is the second-choice modality if the problem is well seen by other methods. If the lesion is best seen by CT, then CT is the modality of choice.

Indications

With renal masses virtually all authors agree that there is no indication for biopsy of a simple renal cyst that is

unequivocal on either CT or ultrasound. The basic indication is the presence as an indeterminate mass in which distinction between a benign and malignant mass is important. In most cases only an aspiration needle is indicated. In some cases when the cytologic sample does not provide adequate histologic data (assuming the bolus dynamic scan shows the mass to be avascular), a cutting needle should be used.

In most such patients the approach is directly posterior, with the trajectory chosen to avoid the erector spinae muscle if possible (this muscle can be painful and it can deflect or bend the needle). As in other areas it is important to anesthetize the renal capsule locally.

Cystic Masses

Several points should be made about aspiration of the renal cyst. Following aspiration of fluid, either diluted urographic contrast material or air may be injected (Fig. 61-83) to define the thickness of the wall. When there is a central mass or wall thickening within a cystic mass, try to sample the irregular wall or solid portion of the mass. In such cases the fluid may be cytologically negative, yet a sample from the mass may be positive.

Solid Masses

Sampling of the solid renal mass is similar to that of masses in other organs. A bolus dynamic scan must be performed to assess vascularity. In most cases if the mass has a slight increased vascularity, aspiration is quite safe (Fig. 61-84). An avascular mass can be biopsied with a large cutting needle if clinically indicated and a specific tissue type is

Other Tips

Several technical points may be helpful. First, when approaching a small mass, perform the procedure in two steps. The first step is to carefully position the needle immediately adjacent to the area being sampled. Several initial approaches may be needed in this way because the kidney is mobile, and with variable respirations a small mass may move in and out of the slice. After the needle has been confirmed adjacent to the mass, "pop" the needle into the mass. If the needle is pushed slowly toward the mass, it may deflect because the bevel of the needle may slide over its curved surface. (I have seen a simple cyst deflect an 18-gauge needle 15 or 20 degrees if pushed slowly.)

Second, when a small renal mass is quite mobile with respiratory motion, place the patient in an ipsilateral decubitus position and approach the mass posteriorly. The weight of the viscera will partially immobilize the diaphragm and the mass.

Results

The accuracy rate for diagnostic aspiration of renal mass is almost 100%. The results of CT aspirations are not much different from results appearing in the older literature on fluoroscopic aspirations except, because simple renal cysts are easy to diagnose by imaging, the number of diagnostic

Figure 61-83. A, A patient with a small cystic mass on the left kidney (arrow) was scanned with the left side down. The weight of the abdominal viscera partially impairs movement of the diaphragm, making such masses more immobile. During this initial approach, the needle deflected from the cyst. B, Scan shows repositioning with needle “poised” adjacent to the mass. The bevel was turned downward to deflect the needle up. C, Puncture of cyst was successful, and clear fluid was extracted.

Figure 61-84. Solid tumors of the kidney are occasionally aspirated. The needle is accurately positioned into the mass.

aspirations is fewer and the percentage of solid tumors is higher.

A comment about aspiration of small adenomas is appropriate. As with the adrenal gland, normal-appearing cells can be recovered from a renal adenoma, but the significance is remarkably different. In the kidney, some believe the adenoma is the precursor to renal cell carcinoma. Consequently, unlike with adrenal adenomas, the recovery for renal tubular cells from a mass indicates a need for surgical removal.

Complications

The complications related to such procedures are quite low, and I have had two. One hematoma occurred during the biopsy of a renal mass close to the hilum, suspected of being a focal lymphoma. In this case a cutting needle was used, and the sample was very close to the segmental arteries. A hematoma developed that required neither surgical intervention nor the administration of blood.

A potential complication mentioned by clinicians is the possible occurrence of needle-tract seeding, for which I can find only one reported case in the literature. However, a carefully controlled study by Von Schreeb³⁹¹ compared the outcome and complications in two groups of patients with proven renal carcinoma. There was no difference in the complication rates, the morbidity rates, or the mortality rates between the groups (and no needle-tract seeding in 75 cases of carcinoma that were sampled).

Renal Parenchymal Biopsy

Renal parenchymal biopsies should be performed only in those cases that preclude the use of ultrasound guidance. In these cases the Tru-Cut needle should be used, but unlike for other areas, no bolus injection is needed. Choose an entrance site and trajectory to avoid the erector spinal muscle for reasons noted earlier in the retroperitoneum section. Unlike in the blind renal biopsy, it is not necessary to “target” the lower pole of the kidney. A good-quality sample avoiding the segmental vessels may be obtained

Figure 61–85. Because the goal of parenchymal biopsy is to recover glomeruli and not produce bleeding, one tries to sample the most peripheral cortex. This scan shows the gap of needle in the most peripheral cortex for sample. The central area should be avoided to prevent inadvertent injury to segmental arteries.

(with more cortex and glomeruli) by choosing an oblique placement within the cortex (Fig. 61–85). In this fashion the medullary region of the kidney, which contains the renal vessels, can be avoided.

The bleeding complication rate from parenchymal biopsies is fairly high, varying in some reports between 5.2% and 8.8%. Sateriale and Cronan³⁴⁸ reported a number of risk factors related to renal biopsies, including hemodialysis, sex, site of biopsy, and treatment with DDAVP (Table 61–7). There is no question that biopsy of renal parenchyma is more dangerous than other procedures; even if the best device and technique are used, serious complications can occur.

There is some controversy among authors about what size needle is most effective for the diagnosis of diffuse renal disease. Although some authors have claimed that an 18-gauge needle is sufficient for assessment of renal pathology, most agree that a larger-caliber needle is better. Mostbeck et al²⁸⁹ compared 18- and 16-gauge needles and

found the 16-gauge needle to be more effective. In our hospital, the pathologists and nephrologists report that a 14-gauge Tru-Cut needle is superior to other devices.

Adrenal Biopsy

Adrenal biopsy by CT guidance is easy, and the indications vary among different institutions. Either an aspiration or cutting biopsy can be performed using different approaches as described. A number of authors have reported on CT-guided biopsies of adrenal masses.^{24,29,69,168,169,171}

Indications

If a patient with a malignant or infectious process has an adrenal mass and if confirmation of the process will change the management of the patient, a biopsy should be performed. Although most adrenal masses that are 3 cm or less are benign nonfunctioning adenomas, there is no method other than cytologic or histologic sampling that can prove this.

These principles have been confirmed by numerous authors, including Candel et al,⁴⁵ Lumachi et al,²⁵⁴ Silverman et al,³⁵⁵ and Welch et al.³⁹⁹ Candel et al⁴⁵ showed clearly that lesions greater than 3 cm have a high probability of malignancy. Even those less than 3 cm had a 13% chance of malignancy. In the setting of a patient with even a small adrenal mass and a lung cancer, biopsy should be performed.

Contraindications

The contraindications for the adrenal gland are the same as for other areas in regard to access or increased vascularity, except for one addition. I believe that a pheochromocytoma or other functioning tumor should not be biopsied. It is well-documented that manual manipulation can initiate a hypertensive crisis; therefore, it seems logical to assume that needling such a tumor might create a similar problem. Thus if a patient has any clinical symptoms of a functioning adrenal tumor, a biopsy should not be done until a laboratory test for catecholamines is performed to exclude a functioning tumor. Despite several uneventful aspirations (unreported from other institutions), two deaths have been reported in the literature (one pheochromocytoma and one hemangioma).²⁶⁸

As an additional precaution against a potential problem it is prudent to have an intravenous alpha blocker available in the department for use should such a lesion be inadvertently sampled and a hypertensive crisis develop.

The validity of sampling even the most subtle mass in a patient with a malignancy is best emphasized by the experience of Pagani.³¹⁷ In his series of patients with small cell lung tumors, he sampled normal-appearing glands and actually recovered malignant cells in a significant number.

Needle Selection

The choice of needles for this organ is the same as for other areas, but commonly an aspiration type must be used

Table 61–7. Factors Affecting Hemorrhagic Complication Rates after Renal Biopsy

Factor	Hemorrhagic Complication Rate (%)*	Increased Risk of Hemorrhagic Complications	P Value†
Hemodialysis			
No	5.9 (13/220)	—	
Yes	24.0 (5/21)	×4.1	<0.025
Patient sex

Figure 61-86. Oblique biopsy of the adrenal gland can be performed if the mass is large enough and the anatomic structure is suitable. This scan shows a mass in the right adrenal gland, which can be approached by a retroperitoneal approach without traversing liver or kidney.

because of the anatomy. In many cases an aspiration needle will be required because either another organ must be penetrated or the trajectory is too close to other structures. In unknown disease if a safe access is available and other factors are appropriate, I will use a large cutting needle.

Approach

There are four different anatomic approaches in biopsying an adrenal mass: an oblique-angled approach, a direct posterior paraspinal approach, a transrenal route, and a transhepatic approach. The first and most desirable approach uses an oblique angled pathway that avoids all intervening structures (Fig. 61-86). This approach is ide-

ally suited for either cutting or aspiration needles because all structures are avoided and it can be used on either the right or left side. However, this approach is technically difficult and requires an entrance site below the level of the lesion. On the right side the angled pathway is between the right lobe of the liver and the kidney, and on the left side the pathway transverses the retroperitoneum behind the tail of the pancreas, medial to the spleen and anterior to the kidney. Sometimes, having the patient in an oblique position expedites this approach. This approach, as well as the next, is suited to aspiration- and cutting-needle procedures.

The second most desirable approach, which is probably the easiest to execute, is a posterior paraspinal route that traverses the crura. This is a straightforward method usable by almost all interventionists because it does not require an angled approach. If a paraspinal approach is taken, an aspiration or a cutting needle can be used (Fig. 61-87).

The next most desirable approach, which is limited to an aspiration needle, is the transrenal approach. This approach is quite direct (Fig. 61-88). It is appealing for several reasons. Literally thousands of aspiration procedures have been performed on renal cysts in kidneys without significant problems, so a transrenal approach for the adrenal is equally safe. If a complication occurs, it is confined to the retroperitoneum, making diagnosis and treatment easier than if a pathway crossing the peritoneum and retroperitoneum is used.

The last approach for the right adrenal gland is a transhepatic approach, which has been proposed by several authors.³³³ This approach can be used with the patient in a supine or oblique position. If the transhepatic approach is chosen, I prefer to perform the procedure with the patient in the decubitus position. By doing this, the liver shifts anteriorly and a shorter pathway through the liver is possible. Theoretically, this should present fewer problems than if a long path through the liver is taken with the patient supine. On the left side, transpancreatic or transsplenic routes should be avoided because of the high risk of complications.

Figure 61-87. A, Sampling of adrenal masses can be accomplished best by placing the patient in ipsilateral sidedown position to immobilize the mass. The entrance site should be at the junction of the transverse process and the rib. The local anesthetic should be amply applied. B, At the level of the diaphragmatic slip, more local anesthetic should be given because movement would move the needle. C, Final placement of the needle tip into the gland. Final adjustments can be made by turning the bevel as previously described.

Figure 61-88. A, Angled transrenal aspiration biopsy of a left adrenal mass is seen. Entrance site for the needle (*arrow*) is below the costophrenic angle at the level of the kidney (K). B, This scan shows the next level above the entrance site. The needle (*arrow*) is passing through the upper pole of the kidney (K). It is important to avoid the costophrenic angle (*curved arrow*) and the medial portion of the spleen. C, This highest scan shows the needle tip in the adrenal mass (*arrow*).

Asymptomatic Adrenal Masses

One question frequently asked is how a mass 3 cm or smaller should be managed,²⁰⁵ with the knowledge that in most cases such masses are benign nonfunctioning adenomas. In my opinion such lesions should be observed or sampled based on the clinical situation. If a patient is asymptomatic without proven malignant or inflammatory disease, no biopsy is needed. If a patient has a proven pathologic problem and involvement of the adrenal gland changes the patient's management, I believe a biopsy should be taken. According to our experience and others,⁶⁹ a cytologic sample will show the presence of normal adrenal cells in nonfunctioning adenomas or hyperplasia, thereby excluding the possibility of a malignant or inflammatory disease. If the cytologic interpretation raises any question about the benign nature of the adrenal cells, further exploration is needed.

Accuracy

The accuracy of CT sampling of adrenal masses is quite high. Heaston et al¹⁶⁸ reported a series of 14 cases and had correct results in 18 patients without complications. Bernadino²⁵⁻²⁹ reported a series of 50 cases with an accuracy rate of 83%. They had an 11% complication rate

overall, with serious complications requiring blood transfusions in 3.5% of cases. Silverman et al³⁵⁵ reported a positive predictive accuracy of 96% and a negative predictive accuracy of 91%. Obtaining benign tissue was a high indicator of benignity. Lumachi et al²⁵⁴ in 2001 reported definitive diagnosis in 97%. The authors discounted the risk of sampling pheochromocytomas, to which I strongly object (see earlier section on contraindications).

Complications

A number of problems have been reported. Bernadino et al,²⁵⁻²⁹ using a transhepatic approach in a reported series of 50 patients, had an overall complication rate of 11%, with a serious complication rate of 3.5%. Two patients required blood transfusions. Pagani³¹⁷ reported a case of pneumothorax that required chest tube placement. Heaston et al¹⁶⁹ and our group, using an indirect approach that attempted to avoid other structures, had no significant complications. There have been two deaths reported (see section on contraindications).

More recently, other authors have reported their experience with complications. Kane et al²⁰¹ reported a 6% incidence of severe pancreatitis when the left adrenal gland was sampled with aspiration needles, using an anterior transpancreatic approach. Mesurolle et al²⁷⁴ reported 6

cases of pneumothorax in a series of 44 patients. Mody et al.²⁸² reported an overall series of 44 patients, in which complications occurred in 8.4%. These authors reported 7 cases of complications (2 pneumothoraces, 2 severe pain, 3 hematomas, and 1 needle tract metastasis). It was also noted that 5 of the 7 complications occurred with a 22-gauge needle.

In view of the large number of reported complications, I believe our conservative approach is warranted. To date we have had no complications from adrenal biopsies, except two pneumothoraces, over the past 25 years. After the adoption of the transcrural, paravertebral approach, no pneumothoraces have occurred.

Mesenteric Mass

Our approach for mesenteric masses is similar to that for all other areas, and the results have been equally successful and safe.

As in other areas, if there is a possibility of penetrating a loop of bowel, a small aspirating needle (20 gauge) is used. If the mass can be approached without penetrating a bowel loop and the other criteria are met, a 14-gauge Tru-Cut needle can be used. Of course, a bolus injection should be used to assess the vascularity of the lesion before the biopsy (Fig. 61–89).

When using the cutting needle, both oral and intravenous contrast material can be helpful in opacifying the normal bowel so that it can be avoided. In addition, try to have the entire gap within the mass that is being biopsied. If a part of the cutting needle overlaps within the peritoneum, some of the abundant small vascular network of the mesentery or omentum may be cut, causing a hemorrhage.

Spleen

The spleen is an area that represents uncharted territory because of the lack of experience and the significant prob-

lems other physicians have had with inadvertent injury to the spleen. From surgical and clinical information, it is obvious that the spleen is very vascular and can be easily severely injured. Because of these previous experiences I believe a larger body of information should be collected before the sampling of the organ can be recommended on a routine basis.

Over the last 12 years I have sampled a number of lesions in the spleen, both cystic and solid, without complication. I have not published or presented the information because I am not convinced that the benefit sufficiently outweighs the potential risks for widespread application. This is one of the few areas I think should be left to academic centers until more information is obtained.

Recently an additional report on splenic biopsy was reported by Keogan et al.²¹¹ In their series of 18 patients they performed 20 biopsies. They used a variety of needles and achieved an accuracy of 88.9%. Although the authors conclude that this is a safe procedure, I believe the experience is not sufficiently large to recommend it as a routine procedure.

Pelvis

The pelvis is a frequent site for biopsy with CT guidance because of the frequency of gynecologic, urologic, and colonic pathosis.^{43,408} All of the general principles for clinical indications—needle selection, bolus dynamic scan, and anatomic considerations—apply in this area, with some qualifications.

Indications

Indications for the pelvis are varied; some are well-defined and others are somewhat nebulous. Clearly defined entities that should be sampled include metastatic tumors from the colon, bladder, prostate, or other organs. The safety and benefit of sampling primary tumors in these areas have not been documented, so generally I do not biopsy primary ovarian tumors unless the patient is considered incurable. One would not want to potentially “seed” the peritoneum in an operable patient.

Approach

The approach to be used depends on the location of the abnormality (i.e., whether it is high in the pelvis, at the level of the iliac crests, or low in the pelvis near the pelvic floor).

Anterolateral Approach

When abnormalities are in the upper portion of the pelvis, an anterior or anterolateral approach may be used. At this level, it is not possible to pass a needle posteriorly because the bony structures are intact posteriorly. When a mass is large enough to push anteriorly, access is quite easy because the bowel has been pushed laterally. When masses are obscured anteriorly by bowel, having the patient lie on either side will allow the bowel to move, permitting

Figure 61–89. Biopsy of small, mobile masses in the peritoneum is possible, but one must adjust the bevel of the needle as required and insert it quickly to prevent movement of the mass.

access for a needle placement. When a loop of bowel is partially obscuring a pathway, one can push the needle slowly and the loop of bowel will typically be pushed aside.

Sometimes in the pelvis an injection of carbon dioxide may be useful to displace loops of bowel away from the iliac vessels and psoas muscle. When such procedures are performed, the needle is placed in the small space between the loop of bowel being moved and the lateral structures (see earlier section on tissue retraction) (see Fig. 61–38).

Lateral masses can be approached with a pathway parallel to the iliac crest, with the needle directed either medially or laterally to the iliac vessels and femoral nerve. The vessels can be identified by injecting contrast material for opacification. The femoral nerve lies in the small “notch” at the margin of the psoas and iliac muscle.

When significant expertise is developed, one can sample

masses or nodes even closer to the vessels. It is always important to recall the importance of using the bevel of a needle to pass by a vessel. In some circumstances, one can even pass a needle between the artery and vein to reach a subtle mass (Fig. 61–90).

Posterior Approach

The posterior approach through either sciatic notch is suitable for the sampling of any presacral mass^{42,318} (Figs. 61–91 and 61–92). See Fig. 61–38, which shows technique for movement of bowel. As with other regions a guidance cannula can be quite helpful to expedite the procedure and ensure precision of needle placement. When performing the procedure through the notch, be careful to avoid the sciatic nerve and the margins of the bone. Inadvertent needle puncture of these areas can be quite uncomfortable.

Figure 61–90. A. A mass (M) is located posterior to artery and vein, making approach rather difficult. B. A cannula of coaxial system and Chiba needle is noted anteriorly to the space between the iliac artery and the psoas muscle. The bevel was turned toward the artery to permit safe passage of both instruments past the artery. C. The Chiba needle was inserted beyond the cannula and a sample was taken. D. The Chiba needle was replaced with a small-caliber cutting needle (Tenmo). This could be safely performed because the cutting gap was beyond the vessels with the Chiba needle and cutting needle inserted.

Figure 61-91. Pelvic biopsy of a patient with deep mass (M). In this case there is a large mass located posteriorly. This was approached through the sciatic notch. I consider this approach less optimal than the anterior lateral approach because of the pain associated with the margin of the notch and the nerve. If the patient experiences pain down the sciatic nerve, the needle should be moved.

Also avoid the area of the gluteal and hemorrhoidal vessels if collateral blood flow has produced pathologic enlargement.

Choice of entrance point is important to avoid impingement against the sacrum because there is a discrepancy between the apparent location of the sacrum as seen on the CT image and its real location. Since the anterior posterior and the lateral margins of the sacrum are tapered, there is a significant partial volume error created on the CT image of the sacrum. Carefully palpate the sciatic notch before any needle insertion because the margin of the bone is more lateral and caudad than would appear on the CT image. With the information from the palpation of the

Figure 61-92. Biopsy of a presacral mass (M). Note that the position of the lateral margin of the sacrum (arrow) can be deceptive. Because of the tapered edges, the margin is more lateral than one might expect. Careful palpation of the site should be performed to prevent any undue discomfort. The sciatic nerve (curved arrow) should always be avoided if possible.

notch, the location of the notch can be anticipated better and the discomfort associated with the procedure can be minimized.

Accuracy

There are several articles from two perspectives in the literature about the accuracy of CT-guided procedures in this area. The first article on this topic from my group examined the accuracy of percutaneous procedures relative to surgical biopsies. We⁴¹⁵ found that in patients percutaneous procedures were more successful than was the surgical approach (either perineal or peritoneal). Butch et al³⁴ reported a series of CT-guided procedures evaluating the overall diagnostic accuracy, correctly diagnosing 15 of 19 cases of neoplasm.

Complications

No complications have been reported to date. The only difficulty has been some pain associated with inappropriate placement of needles through the sciatic nerve or local trauma to the sacrum.

Therapeutic Procedures

CT can be used quite readily for performing a number of aspirations and drainages in different portions of the body. By far the greatest number of drainages that will be performed are those on abscesses, but occasionally cysts, lymphoceles, pseudocysts, bilomas, or other fluid collections may be drained.

Lymphoceles

Lymphoceles are collections of lymph fluid, usually caused by the local disruption of lymphatic vessels after surgery. The appearance of these lymphoceles is indistinguishable from abscesses appearing as well-delineated fluid collections (Fig. 61-93). These fluid collections spontaneously resolve without any type of therapy intervention when new lymphatic channels open.

There are only two valid indications for intervening when such a fluid collection is found. If a clinical suspicion of an infection exists, a diagnostic aspiration is indicated. There is no rationalization for catheter insertion in such cases unless purulent material is present. Inserting a catheter may cause secondary infection, but in most cases the cavity will close after the infection has resolved. The second indication is when the lymphocele is producing obstruction of the urinary tract or gastrointestinal tract. In such cases needle puncture and catheter insertion are the same as for the other fluid collections. Another point to be made is that a lymphocele will persist in draining fluid until the lymphatics open new channels, whether a catheter is present or not. Removal of the tube will result in reaccumulation of lymph fluid, if such channels have not formed.

When a lymphocele has been drained for one of these

Figure 61-93. A, A large lymphocele (L) is noted in the left side of pelvis following kidney transplant. Access to the collection is impaired because of the proximity of bladder (B) and the clips from surgery. B, Positioning of the patient with the right side down increases the space for the needle trajectory (arrow) so the cyst can be punctured without penetration of the bowel or bladder, which could potentially introduce infectious agents. C, Radiograph shows the catheter in the lymphocele (arrow) and the ureter (U).

reasons, some radiologists have instilled sclerosing material such as tetracycline to speed resolution. In recent years, numerous authors have reported the use of a variety of agents that sclerose lymphoceles. These have included doxycycline (Caliendo et al⁴⁴), bleomycin (Kerlan et al²¹²), ethanol (Zuckerman and Yeager⁴²⁵), and Betadine (Gilliland et al¹¹² and Montalvo et al).²⁸⁴

The results of such sclerosing procedures have been variable and in many cases, surgeons will default to internal drainage. Laparoscopic procedures have been reported by Gruessner et al¹³² and Hamilton and Winfield.¹⁶³

Renal and Liver Cysts

Deciding to Sclerose

The decision to sclerose a large cyst in the kidney or the liver is not an easy one for several reasons. First, any procedure—no matter how benign—can have adverse side effects, and the use of these sclerosing agents are not without their danger. Second, it is an unusual circumstance when a cyst produces physical discomfort, so I am highly selective. To make sure a patient with a cyst is experiencing symptoms and not just having psychological overlay from “knowing” a cyst is there, I do the following intermediate step: On the patient’s first presentation, I will only aspirate the cyst without sclerosing agent. The instructions to the patient and the purpose in this is as follows. In some cases a cyst will not come back, so if it does not and the patient is not symptomatic, the patient will not return. If the patient comes back and the repeat scan shows no recurrence of the cyst, then there is no reason to do anything, and one can be confident that the symptoms are not related to the cyst. If the patient comes back and the cyst is back, then this proves the symptoms are from the cyst and worthy of sclerosis.

True cysts with endothelial linings can occur in many organs, including the kidney, liver, pancreas, and spleen. They all have similar appearances and are seldom punctured for diagnosis or drained, unless they are producing

symptoms or are suspected of being either infected or neoplastic. The mere presence of a cyst in an organ is no reason for sclerosis, but in some cases cyst size may be so great as to impair respiration, produce pain, obstruct the portal structures, or obstruct the renal collecting system.

The diagnostic puncture of such cystic cavities is quite easy and is performed in the routine fashion using either the 20-gauge needle or the Teflon-sheathed 18-gauge needle. The trajectory should be planned so that a “cuff” of tissue is included in the pathway of the puncture. If this is not done, the risk of rupturing the cystic cavity into an adjacent space exists because the walls can be quite tense and can tear. Obviously, if this were a simple cyst, ill effects would not be a concern. However, if the cystic lesion is an abscess or a tumor, a complication could result. Avoiding leakage is also important if alcohol sclerosis is to be performed to prevent back-leakage of alcohol into the peritoneum.

If the decision is made to drain the cyst and prevent reaccumulation, simple aspiration will usually not suffice because the endothelial lining that produced the fluid will continue to fill the cyst. The only way to stop this from recurring or growing is to inject a sclerosing agent such as tetracycline or ethyl alcohol. Our choice is alcohol because it is a potent local irritant, it has no idiosyncratic effects, and it is easily metabolized. Since surgeons have attempted for years to eliminate these by simple injections with varying success, I expect that this simple injection method will have equal success as a radiologic procedure.

Our approach has been different from that of other authors who have simply evacuated a portion of the fluid, injected alcohol equivalent to 25% of the volume, and then repeated the injection several times. I object to this method for two reasons. The alcohol is diluted significantly; this limits its local effect of destroying the endothelial lining. Because large volumes of alcohol may be needed in large cysts, there is the possibility of administering a large systemic dose. My approach begins with the insertion of a small 5-French pigtail catheter as a conduit (Fig. 61-94). Before any further manipulation of the cavity, a contrast

Figure 61-94. A, Scan shows two large cysts that are separated by a septum (arrow). The needle was inserted to permit puncture of both cysts. Note that the path was chosen to provide a cuff of normal liver to prevent the spillage of either cyst fluid and alcohol when it is injected at a later time. B, Radiograph shows the insertion of wire and catheter into the cyst cavity. The cyst is left to drain for several hours before the instillation of alcohol (see text).

injection is performed to ensure that there is no communication with the biliary or urinary system. If the system communicates, the procedure must be aborted, because injection of alcohol would sclerose the system. I then evacuate all of the fluid and apply suction until the walls are opposed.

Following this I make multiple injections of small amounts of alcohol as follows. I inject an initial volume of 15 mL of alcohol and leave it in place for 5 to 10 minutes. During this time I have the patient rotated into various positions, lateral and prone, to ensure that the alcohol bathes all surfaces of the cyst. After 10 minutes I attempt to recover the alcohol injected. If the alcohol cannot be recovered, I will inject an additional 10 mL and pull the catheter. If the alcohol can be recovered, I aspirate out as much of the alcohol as possible and then reinject 15 mL and repeat the process. The alcohol is removed a second time and a third aliquot of 15 mL of alcohol is injected and left in place. The alcohol that is removed will show a remarkable change when it is removed. The color changes from crystal clear to very cloudy, turbid, and pink. The change is due to the sloughing of cells into the fluid as it damages the inner surface of the cyst (Fig. 61-95).

After this procedure there is really no need for repeat studies because if the patient remains asymptomatic, the cyst is resolved. If the cyst returns, the patient will return with symptoms and the procedure can be repeated with slightly larger amounts of alcohol if desired.

I believe this conservative method is better than the large-volume methods used by other authors. Such large volumes invariably result in some intoxication of the patient and can actually put other portions of the liver at risk because of the local toxicity of the alcohol. When the readers go to a conference, they will be amazed at how cases being demonstrated using the high-volume method will show destruction of other liver lobes; the lecturers seldom make note of that in their presentation.

Another approach has been offered by Cellier et al.⁵⁰ In a group of five patients, the authors performed the following technique. The cyst was punctured and half of the cyst content was aspirated. A single dose of 100 to 500 mg of minocycline hydrochloride was injected and left in place. At follow-up four of the five cysts had resolved.

Pancreatic Pseudocysts

Pseudocysts of the pancreas are collections of necrotic debris, inflammatory material, and digestive enzymes that require treatment because they are associated with a number of complications. The optimal time to drain these is after 6 weeks and before 13 weeks. Approximately 6 weeks should elapse before any procedure because a high percentage ($\geq 25\%$) may actually disappear spontaneously. With those that have gone untreated longer than 13 weeks, some authors have reported a high incidence of infection, rupture, or bleeding, all of which can be catastrophic. To prevent such complications, as well as the symptoms associated with these problems, effective treatment is indicated. An important point is that only fluid collections, and not poorly defined phlegmons or edema collections, should be drained.^{131,130}

Surgical Versus Radiologic Methods

If one carefully reviews the literature, there are numerous articles that discuss the merits of surgical approaches versus radiologic ones (discussed later). In general, the antagonists and protagonists of each position tend to emphasize several points on either side of the argument. Generally, the percutaneous procedures tend to require a longer time for resolution than surgical ones but radiologic procedures tend to have fewer complications and lower morbidity. One of the largest series reported in the surgical literature was by Heider et al.¹⁷⁰ In their retrospective study

Figure 61–95. These three images (A to C) show the gradual reduction in the size of a cyst (C) that has been sclerosed with alcohol. The reduction in the cyst occurs over many weeks.

of 173 patients, percutaneous methods were inferior to surgical treatment. They reported successful treatment in only 42% for percutaneous and 88% for surgical treatment. The other factors were worse outcome for percutaneous methods with mortality 16% versus 0%, complications 64% versus 27%, and longer hospital stay 45 days versus 18 days. In my opinion the merits of various methods depend on the individual physicians at each site and the selection criteria for the methods. The best examples of this controversy can be appreciated by noting two articles from the same institution in the same year by Adams and Anderson² and Criado et al.^{60a} The two groups from the same institution seem to contradict one another in their support of surgical or radiologic methods.

Suffice it to say that each institution tends to have its own idiosyncracies, and the skill levels of each group probably differs from one center to the next. Depending on the local talent and experience produces a preference for surgery or radiology.

Three methods of treatment have been reported, and after a number of years of development the advantages and disadvantages of each are well known.^{13,77} These methods, in chronology of development, are aspiration, external drainage, and internal drainage. None of the reports in the radiology literature reveals the deficiencies of the methods. An impression is given that each method has solved the problem. In my extensive experience with the different treatments of pseudocysts I have formed personal opinions

of their various roles, and I have found each method to have some merit but also some shortcomings. With each succeeding method the results have been better, but there remains a subset of patients who are not “cured” by our percutaneous methods and who therefore require surgical treatment. Each of the methods are described, and the benefits and disadvantages are noted from our perspective.

CT is ideally suited for any of the methods. It is the best modality for visualization of the anatomy and instruments so that avoidance of uninvolved structures is possible. Avoidance of small bowel and colon is important because secondary contamination can occur. Furthermore, with CT, pseudoaneurysms can be accurately diagnosed and avoided. Life-threatening hemorrhage has occurred when these structures were inappropriately penetrated.

Observation

When a pseudocyst is first detected by imaging, it is probably reasonable to observe the pseudocyst for a period because a significant number spontaneously resolve. Sanfey et al¹³⁴⁶ reported that in their series of 97 cases of inflammatory pseudocysts, 32% resolved spontaneously. If the patient is asymptomatic, then observation for 4 to 5 weeks before attempting treatment is probably appropriate.

Aspiration

Simple aspiration of a pseudocyst appears to work in slightly less than 25% of cases, but it is advantageous

because of its simplicity. This procedure can be performed with the standard methods described previously and with little or no risk (assuming one avoids bowel loops and vascular structures). The procedure is so simple that most can be performed on an outpatient basis, as noted earlier. Some have recommended that several aspirations may be required over a period of weeks or months. The subset of pseudocysts most likely to be cured by this method is that occurring after a localized and minor leakage from the pancreas after a surgical procedure.

External Drainage

This type of drainage is analogous to the external drainage performed for abscesses. With this method various structures are avoided, and a catheter that drains to the external environment is put in place. Some authors have reported good results using this method, but in our experience a fairly high percentage will persist or recur. The risk of a permanent fistula or secondary infection also exists. Although the literature on this problem does not indicate significant recurrences, we have performed such procedures for more than 20 years (Fig. 61–96) and found the recurrence rate to be similar to the aspiration method. Indeed, if this method were so effective, the transgastric method would not have been developed.

Two subsets of pseudocysts have responded quite well to this mode or the aspiration mode of therapy. Well-defined pseudocysts that are secondarily injected are well suited for percutaneous external drainage.^{97,388,389} In those patients who have a pseudocyst secondary to external or surgical injury, the pseudocyst can easily be treated by aspiration or external drainage.^{14,20,34} In most of the cases I have treated and in those reported in the literature, such drainages are uniformly successful without any sequela or recurrence.

Transgastric Drainage

The most promising method for draining such pseudocysts is a transgastric approach as described by Nunez,³⁰⁷ Bilbao,³¹ Bernadino et al.,²⁸ and Ho.¹⁷⁵ With this method a

trajectory is chosen that includes the walls of the stomach and the pseudocyst in the lesser sac. The catheter provides internal and external drainage until such time as the pseudocyst resolves.³¹

In the largest series by Nunez,³⁰⁸ eight pseudocysts in seven patients were successfully drained. The length of drainage was 3 weeks in six cases and 6 weeks in two cases. No recurrences were noted, but the length of follow-up was not mentioned.

Modified PEG Drainage

We have stopped using Nunez' method because of clinicians' concern about possible gastric spillage into the peritoneum. We have devised a modification of this method that eliminates this potential problem and that has been well received by the clinical physicians. After the decision has been made to drain the pseudocyst, we have the endoscopist insert a percutaneous endoscopic gastrostomy (PEG). The tube used differs slightly in that the end of the gastrostomy tube is cut off. With this PEG securing the stomach wall to the abdominal wall, we use it as a conduit through the gastric space into the pseudocyst (Fig. 61–97). A Teflon-sheathed needle is inserted through the gastrostomy through the posterior stomach wall into the pseudocyst. This has worked well because the entrance point is secure and there is no risk for peritoneal soilage. The trajectory is easy because the gastrostomy site in the skin serves as a fulcrum and one can angle the needle to any point on the posterior stomach wall. The distance is short, and angulation is simple. Once the pseudocyst has been successfully punctured, a catheter is inserted using the Seldinger technique. Because a 20-French gastrostomy tube can be inserted, angiographic catheters as large as 9- or 10-French can be used to penetrate the pseudocyst.

In our experience the short-term results of the transgastric method are quite good. Unfortunately, in the long term (up to a year after the removal of the tube), some will recur. It has been our experience that leaving the tube in for about 6 to 8 weeks is sufficient. If the cyst remains or recurs after this, then surgical treatment is probably needed.

There are two advantages of the transgastric method.

Figure 61–96. Percutaneous transgastric drainage of pseudocyst is a viable option for drainage. A, This scan shows the needle trajectory through the stomach into a large retrogastric pseudocyst. B, Later scan with a catheter in place shows remarkable resolution of the pseudocyst.

Figure 61-97. A, Scan shows pseudocyst (C) anterior to the pancreas (P). Note the percutaneous endoscopic gastrostomy (arrow) anteriorly in the stomach. B, Scan shows the needle (curved arrow) penetrating the end of the tube into the cyst, and the wire (arrow) looped in the pseudocyst. C, Radiograph shows a large tube traversing the stomach and located in pseudocyst; contrast medium defines the stomach (S).

First, residual or leaking pancreatic juice can exit into the stomach, thereby preventing a fistula. Second, the enteric flora can colonize the pseudocyst, thus permitting inflammatory reaction and better closure of the cavity.

Pancreatic Fistula

Rarely, a pancreatic fistula may result after tube drainage of a pseudocyst. Of the several approaches that might be used, only one has been reported. First, some authors have used the hormone somatostatin to decrease the exocrine output of the gland.²⁸⁷ The results have been variable, however, and the medication is quite expensive. Another method, proposed by Haaga and Stout, is the use of a biologic glue such as “fibrin glue” to seal such a pathway from a pseudocyst or the pancreatic duct.

A number of authors have evaluated factors that might be indicators of likely success for percutaneous methods. Duvnjak et al⁵¹ reported that pseudocysts with a high amylase content were unlikely to respond to percutaneous methods. These findings may be an indirect observation based on communication with the pancreatic duct; those pseudocysts having direct communication with the duct are more likely to have high levels of amylase. Barthet et al¹⁹ noted that percutaneous methods were less likely to be successful if there was communication with the pancreatic duct.

Other Proposed Adjunctive Management

Morgan et al²⁸⁸ advocated the use of MRI to evaluate fluid collections to assess the presence of large pieces of necrotic debris within fluid collections to determine if percutaneous methods are suitable. Such collections were judged to be not drainable if the material measures more than 1 cm in size.

D’Agostino et al⁶⁵ reported the use of the hormone octreotide to lessen pancreatic secretion and flow during percutaneous drainage. The drug was given in recommended doses and appeared to be beneficial in four of eight cases.

Abscess Aspiration

Percutaneous aspiration and percutaneous drainages guided by CT represent the most significant advance in the care of acutely ill patients since the development of surgical drainage and the discovery of antibiotics. Since the first CT-guided aspiration and drainage (Fig. 61-98) that I performed in 1975 and reported in 1976,¹⁵³ the use of this technique has grown rapidly.* This growth has occurred

*References 111, 158, 191, 210, 300, 319, 322, 383, 390.

Figure 61-98. A, First CT-guided drainage of an abscess (arrow) performed in 1975 by the author. B, Plain radiograph of the abdomen shows a drainage tube in place (arrow). The patient recovered uneventfully. (B, From Haaga JR, et al: Definitive treatment of a large pyogenic liver abscess with CT guidance. *Cleve Clin Q* 43:85–88, 1976.)

because of the increased number of scanners available, the excellent accuracy of CT for the detection of any fluid collection, the high accuracy for guidance, and the popularization of the technique by enthusiasts such as Haaga,^{147, 153, 155} Gerzof,^{106–111} and Van Sonenberg.^{384, 386–390}

Diagnostic Aspirations

Because patients with infectious fluid collections may or may not manifest the typical signs of infection, I believe that if there is even the slightest clinical concern about an abscess, a diagnostic aspiration should be performed. This aggressive diagnostic approach is justified because with careful technique, including avoidance of bowel, a sample can be successfully recovered in almost 100% of cases with little or no risk. In my experience with CT guidance over the last 27 years, I have aspirated more than 500 cases with no secondary infection and with only one hematoma that occurred as a complication.

The diagnostic sampling of fluid collections requires the same planning as that of all of the other lesions we have discussed, but several factors must be kept in mind. The material being obtained may contain viable pathogenic material and can disseminate infection if it is inappropriately spilled or contaminated into sterile spaces. Even though modern potent antibiotics can eradicate any minor spillage of purulent material, great care should be taken not to contaminate sterile areas. Patients may develop serious peritonitis or bacteremia if the inoculum is larger or the organism virulent (or if the patient is immunocompromised by any cause).

A question occasionally arises concerning the interpretation of culture results—that is, how culture results should be interpreted when only a limited number of colonies grow. It is my opinion that any number of colonies involving organisms other than *Staphylococcus* should be considered an infection at least warranting antibiotic therapy based on the culture sensitivities. Depending on the number of bacteria within a fluid collection or the presence of antibiotics, the possibility always exists for a sampling

error that can result in a negative culture or possibly growth of a limited number of pathogens.

Finally, during the aspiration of fluid densities, it is important to avoid traversing gastrointestinal loops. First, a sample taken through bowel may provide spurious culture results. Of course, some claim that presence of mixed flora and absence of a “pure” culture of a single organism can distinguish an abscess from gastrointestinal colonization. However, as has been well documented in the radiology literature, many abscesses are caused by a gastrointestinal fistula that contains many types of organisms. Second, the function of humoral cellular defenses is lessened in a fluid space, so that clearing of bacteria by phagocytes is impaired and a secondary infection might occur if a small inoculum is introduced into a fluid collection.

Mycotic Aneurysms or Infected Vascular Prostheses

Because of the difficult treatment required for infected vessels or synthetic aortic prostheses, it is my firm belief that any patient with such a suspected infection should have a diagnostic aspiration at the earliest time. With both infected prostheses and primary mycotic infections in the infected prostheses we have encountered, the cultures have been positive and reliable. In each of these cases the culture results were critical and helped initiate the expeditious treatment of the problem. With prompt treatment most of these patients survived the surgical therapy. In another group of 10 patients with uninfected grafts, the results were negative. There have been no complications associated with the needle procedures (Figs. 61–99 and 61–100).

Such cases should be approached from the flank, and a pathway should be chosen to avoid the kidney and major vessels. In most instances a clearly defined fluid collection will be seen either adjacent to the graft or between the wall of the aneurysm and the graft. As with other procedures performed from this approach, we try to avoid the psoas muscle, erector muscles of the spine, and the spinal elements to prevent patient discomfort.

Figure 61-99. Diagnostic aspiration of air collection around a prosthetic graft. CT scan shows the patient lying prone. Note the needle penetrating the wall of the aneurysm, which encloses air collection next to the graft.

In such cases, if there is any question about the location of the vessel or prosthetic wall, a bolus dynamic CT scan should be performed. Dynamic CT is highly effective for the demonstration of a vascular problem, even better than Doppler ultrasound and angiography. In one patient with a clotted mycotic aneurysm, only CT correctly showed the vascular nature of the lesion.

Some individuals have raised concerns about possible injury to such an infected vessel, but in our experience this is not a problem. In the more than 20 suspected cases we have aspirated, there have been no complications.

The need for such aggressive expeditious procedures is clear. The mortality rate of untreated prosthesis infection is high, almost 100%. Corrective treatment and surgery can be effective only if initiated early. In some instances, percutaneous drainage of infected prostheses may be effective²⁹ if the infection involves only the midportion and not the anastomotic ends (Fig. 61-101).

Other authors such as Rossi et al³⁴² have also proposed an aggressive approach to the diagnosis and management of these difficult infections. These authors have also advocated percutaneous aspiration for diagnosis of infectious agents as well as palliating the infection with preoperative catheter drainage. We have effectively cured a patient with graft infection using local catheter drainage.

Abscess Drainage

Before CT, percutaneous abscess drainage (PAD) was occasionally performed, but with the advent of CT assistance it has become a routine procedure. CT has been especially useful because it has a high detection accuracy for abscesses and allows accurate determination of the anatomic location and extent of the lesion. Because CT is not impeded by gas or bone, any involvement of peritoneal spaces or anatomic areas can be clearly delineated. This information is absolutely necessary if one is to determine whether an abscess can be drained by a percutaneous method.

Although there was some controversy in the early literature concerning the merits of different guidance systems for drainage, there now appears to be a consensus that CT guidance is the best method available.^{147,230,389}

Perspectives on Abscess Drainages

With a global perspective toward abscess drainage, it is clear that the intent of interventional percutaneous procedures is to at least duplicate the excellent treatment results established by our surgical colleagues. The benefit of percutaneous procedures lies in their simplicity, lower complication rates, and presumably lower overall expense. Recent publications in the surgical literature have illuminated some of the factors that relate to the outcome of both percutaneous and surgical procedures.¹⁶

The benefits of improved detection and localization of

Figure 61-100. *A*, This scan shows postoperative fluid collections around the graft material within the old aneurysm bed as well as in the right flank. *B*, With the patient in the left decubitus position, percutaneous aspiration of fluid around graft was performed. Because *Staphylococcus* is the most common organism, such aspirations may be necessary even if gas is not present. Aspiration of the opposite right fluid collection was performed independently using a different pathway to avoid possible cross-contamination of the spaces, if one space happened to be sterile and one happened to be infected.

Figure 61-101. A, Percutaneous drainage of fluid collection around the iliac limb of a prosthetic graft. Note the fluid collection (arrow) confined by the aneurysm. B, CT scan shows a catheter placed within the fluid collection. Note the opaque contrast medium around the patent graft (arrow) and the air cavity anteriorly within the cavity. C, Follow-up scan shows complete resolution of fluid collection. A small residual amount of gas is left after removal of the catheter. Four months after drainage, the patient continues to be completely well. Urokinase irrigations were used to enhance drainage (see text).

abscess have been documented by Deveney et al,⁷¹ who showed conclusively that the improved localization and intensive care methods have resulted in a greater percentage of drainage success as well as decreased mortality resulting from organ failure. These authors, in a veteran population, studied two 5-year periods (1973 to 1978 and 1981 to 1986) and noted the following. The mortality of the two groups was 39% and 21%, respectively. The successful initial drainage was 55% compared with 74%. Organ failure rate decreased from 52% to 23%. The surgical success rate was 76%, compared with the percutaneous success rate of 72%. The authors concluded that accurate localization and early drainage are the most important factors and that there is no difference in outcome between the surgical and percutaneous methods.

The importance of overall patient status has also been documented by Levison et al.²³⁹ These authors used the APACHE II system to grade patients and follow their outcome. The final results were that mortality was directly related to the APACHE score. Of those with a score less than 15, the mortality was 1.7%, compared with a mortality of 78% when the score was greater than 15. There was no significant statistical difference in outcome between percutaneous and surgical drainages. (One is cautioned not to quote this finding out of context, because the authors subjectively maintain that surgical drainage was better by *absolute* numbers. The finding was *not* statistically significant, however.)

The importance of the immune system has been emphasized throughout this discussion on intervention. Lambiase et al²²⁹ have documented how critical this factor is as it relates to abscess drainage. These authors considered the following states as immunocompromised: absolute neutropenia, human immunodeficiency viral infection, cancer with distant spread, chemotherapy, radiation therapy, lymphoproliferative disorders, diabetes requiring treatment, chronic renal dialysis, splenectomy, and severe alcoholism. They found that with percutaneous abscess drainage the overall cure rate for immunocompromised patients was 53.1% compared with the normal rate of 72.6%.

Patient Selection

In recent years the indication for percutaneous methods has expanded significantly.^{39,48} Unlike most new techniques and procedures in which there is an initial period of enthusiasm followed by either a moderation or a restriction of the method, percutaneous drainage guided by CT has continued to expand its role. The results of percutaneous procedures have been so positive and so widely accepted that the indications and applications have continued to find new application.

To maintain a proper clinical perspective, it is important that the proper patients be selected for curative or palliative PAD procedures^{384,386} and for surgical procedures. Simplis-

tically, one could try PAD for palliation in every patients, but it is not logical to expand its use for patients with certain surgical problems.³⁹ On a practical level, although the role and the indications for percutaneous procedures have expanded greatly, there are still clear indications for surgical drainages.

To anticipate a curative percutaneous procedure, certain clinical and anatomic facts must be confirmed. Patients who have an abscess or abscesses that appear well-defined are suitable candidates if a clear anatomic pathway is available. In the early experience procedures were restricted to those abscesses with only a few cavities. The results with septated abscess has been variable; some drain quite well and others do not (Fig. 61-102). The most plausible explanation for this is that fibrin septa in such cavities may be complete or incomplete: when they are complete, drainage is poor and when they communicate and are incomplete, curative drainage can occur. We have studied the use of fibrinolytic agents in the former cases and have found them quite effective for improving drainage (see later discussion on fibrinolytic agents). Also, the multiplicity of abscesses is no longer considered a contraindication to percutaneous drainage because each site is treated independently.

For the choice of anatomic pathways, we still prefer a clear pathway into the abscess cavity without traversing an uninvolved space or organ. I believe that a routine penetra-

tion through an uninvolved organ is inappropriate because of possible seeding of pyogenic organisms into the organ. Although with the potent antibiotics of today most such procedures appear feasible, I believe that when larger series are collected, the success and complication rate will favor avoidance of uninvolved organs and spaces.

Another important factor to consider is the viscosity of the material in the abscess. If the entire cavity can be evacuated easily after aspiration, percutaneous drainage will probably work. If the material appears to be quite viscous, techniques should be adjusted appropriately (i.e., special attention given to catheter size, catheter placement, and use of an appropriate irrigant). These are discussed in the section on catheter management.

Choosing PAD for palliation is most appropriate. Adequate palliative drainage will reduce the "toxic load" resulting from drainage of purulent material and will usually produce considerable improvement in such patients. Remarkably, some will be cured, but even those who are not will benefit from an improved physiologic state that makes them better surgical candidates.

The appropriateness of percutaneous drainages for abscess associated with entities requiring surgical treatment is an area of significant controversy (discussed later). In the final analysis, however, one must weigh the palliative benefits of PAD against the final curative benefits of surgery.³⁹ Similar views are shared by Dr. Claude Welsh

Figure 61-102. A, CT scan shows a large loculated mass in the right lobe of the liver. Such multiloculated masses may resolve with simple tube drainage. B, Repeat scan after insertion of a catheter. Note that a pathway traversing the liver parenchyma was chosen to lessen the chance of spillage into the peritoneum. C, Sinogram shows the multiloculated cavity within the right lobe of the liver. When resolution of such cavities does not occur quickly, use of urokinase may be helpful.

of Massachusetts General Hospital,³⁹⁷ who noted in an editorial:

Unfortunately, abscesses vary so greatly in many ways that studies with proper, randomized controls would be very difficult to establish. It is far more likely that further experience will lead to greater concurrence between radiologists and surgeons. Thus the letter by Haaga et al. outlines conclusions that appear to be quite closely in accord with our own studies in the Massachusetts General Hospital. *Since Haaga and his co-workers originated the radiologic method, their opinion must be given great respect.*

Indications for Surgery

Some patients are not good candidates for percutaneous procedures and are better suited for surgical drainage. This group consists of patients with fungal infections,⁴¹⁰ infected hematomas, echinococcal disease, surgical disease requiring correction, most pancreatic abscesses, and failed percutaneous drainages.

Patients with fungal abscesses require surgical drainage because there is extensive tissue invasion, necrosis, and mycotic plaque formation with the wall of the cavity. Our experience with several such cases and reports in the literature show that surgical drainage or resection is best for adequate débridement.

Infected hematomas do not drain well because of the extensive amount of fibrin deposition and the protective effects of fibrin on bacteria. Again, as shown from our early experience and from reports in the literature, it is clear that such hematomas have uniformly failed by percutaneous drainage. In our more recent experience, fibrinolytic agents used as a catheter irrigant can improve the drainage of infected hematomas.

Echinococcal disease requires a special approach to prevent spread of the daughter cysts into the peritoneum or other areas. The issues related to anaphylaxis are essentially minimal with appropriate technique, and many authors have now reported on the technique of percutaneous drainage. The specific approach is discussed at the end of the section on abscess drainage.

Finally, for those patients who have had a failed percutaneous procedure, surgical drainage is appropriate. Because of the difference in philosophy among surgeons, radiologists, and institutions, the definition of a failed procedure can be determined only at the local level and not in this text.

Treatment of Abscesses by Aspiration Alone

In recent years there has been introduction of a new approach for abscesses that is somewhat avant garde and may have a role in the future. These techniques have been based on single or multiple aspiration procedures on abscesses, in lieu of drainage tube placement. It is difficult to understand the origin of such techniques, but usually it was based on two factors: (1) lack of safe access to permit catheter insertion and (2) small size preventing catheter placement.

The techniques published recently were by McFadzian et al,^{268a} Giorgio et al,^{114,115} Saluja et al,³⁴⁴ Ch Yu S et al,⁵¹ Wroblecka and Kuligowska.⁴¹¹ The specific details of each

author differed slightly, but most reported single or multiple aspirations of the abscess cavity while systemic antibiotics were given. Wroblecka and Kuligowska⁴¹¹ reported irrigating the cavities with saline. McFadzian et al^{268a} and Giorgio et al^{114,115} also injected intracavitary antibiotics. The authors all claimed high success rates. It should be noted that the authors also reported numerous failures and complications, including transient sepsis, death by sepsis, failure because of enteric fistula, and peritonitis.

Several important points from these papers should be noted. The selection of patients is not consistent, so widespread application of this technique is not appropriate at this time. I disagree with an editorial comment by Miller et al,²⁷⁷ who stated that this might be the biggest advance for abscess treatment in 80 years. The biggest advance was surely the use of CT and drainage methods for treatment. When the first such diagnosis and procedure were made in 1975, patients were literally dying from undiagnosed and ineffectively treated abscesses; current techniques provide remarkable diagnosis and cure, so any major change should be made only when appropriate study has been made. On the other hand, if other authors report similar experience as Giorgio et al,^{114,115} then perhaps this new drainage approach will become a more widely accepted and used method.

It is my belief that these techniques offer a good second-line treatment for abscesses if drainage is not possible. My opinion, however, is that if radiologists use the techniques described in this work and others, the occasion when a catheter cannot be placed is rare indeed. When such cases do arise, the best approach would be to combine the best of all details in these articles. When catheter placement is not possible on the basis of access or size of the abscess, the following technique should be used: (1) aspiration of purulent contents, (2) lavage with saline, and (3) injection of a small dose of antibiotic. The antibiotic chosen should be the one selected from cultures and sensitivities (if available from fluid or blood cultures). Because there are few guidelines, one should probably use close to a single IM or IV dose, and that quantity should be deducted from any daily limit stipulated by the manufacturer or the FDA. It is also important to pay attention to the volume required because one must not inject volumes too large for the cavity. For typical pyogens, when routine broad-spectrum antibiotics are used, the volume will not be an issue. With fungal abscesses, the volume of the dilute drug may be too high, so the dosage will need to be reduced.

Sequential Steps for Drainage

The technique of abscess drainage can be divided into the following steps:

1. Abscess detection
2. Trajectory planning
3. Selection of the guidance modality
4. Diagnostic aspiration
5. Catheter selection and insertion
6. Sinogram and catheter adjustment
7. Catheter management and irrigation
8. Follow-up diagnostic evaluation
9. Catheter removal

Abscess Detection

Detection of an abscess can be accomplished in selected cases by any modality, but CT plays the most critical role. CT is the preferred examination because it is the most accurate of all imaging systems for abscess detection. Not only can CT confirm or exclude the presence of drainable fluid, but it can also diagnose the causative or associated problem. CT can provide valuable information about diverticulitis, tumors, appendicitis, fistulae, infarcts, cellulitis, phlegmons, inflammatory bowel disease, bowel obstructions, or other problems.

If an abscess has been detected by either plain radiography, gallium, or ultrasound, a CT scan should be performed to determine the complete extent of the abscess. The geographic location and degree of involvement are essential

factors in choosing the trajectory, determining the number of catheters required, and anticipating possible difficulties. Although some authors were initially reluctant to accept not only the advantages but the critical role of CT in defining the nature of an abscess, virtually all authors now agree that CT is the modality of choice for the detection, staging, and planning of a drainage procedure. The criteria for drainage have been expanded to include many patients, so the need for accurate detection and staging is even greater.

Trajectory Planning

Trajectory planning is best accomplished by CT, regardless of the imaging modality chosen for guidance. Although as most authors agree it is best to choose the shortest

Figure 61-103. Sagittal reconstruction taken through the lateral portion of the chest, about 3 cm lateral to the midclavicular line. **A**, This scan shows quite clearly the widened space between the anterior ribs compared to the posterior ribs (arrow). Furthermore, you can appreciate how the structure of the ribs actually enhances the cephalad direction of the needle or catheter—there is an upward slope of the ribs. This permits remarkable flexibility in angling the device when inserted through the ribs. **B**, Sagittal reconstruction through the left side of the chest. Note that the anterior diaphragm is much higher than the posterior portion and therefore the muscle slips are much higher anteriorly. **C**, Relationships of the diaphragm can also be appreciated by noting the position of the diaphragm in a patient with an inverted diaphragm. This scan shows what would apparently be a left subdiaphragmatic collection. Examination of contiguous slices suggests its true nature. **D**, Sagittal scan shows how large pleural fluid collection pushes down and forwards the posterior portion of the diaphragm. Note how the anterior portion is virtually stationary because it is higher and less mobile; more anterior approaches are less variable and less prone to motion during the procedure.

pathway, it is also optimal to avoid uninvolved organs and noncontiguous peritoneal spaces.

One of the most problematic areas typically involved includes the supracolic spaces above the mesocolon and below the diaphragm (see peritoneal chapter). The most common are the right subphrenic, left subphrenic, and lesser bursa (sac). To plan the trajectory in these areas, it is critical to understand and appreciate the spaces as they relate to the diaphragm and rib cage.

These relationships can be best understood by noting the spaces between the ribs (Figs. 61–103 and 61–104). The subphrenic collections can be typically punctured and drained without traversing the pleura as suggested by some authors if one uses an angled approach and chooses a trajectory as anterior and lateral as possible. One should never choose an entrance pathway that traverses the pleura; quite candidly, I have never encountered an abscess that required such an approach. Improved delineation of anatomy and access to these spaces can be optimized by having the patients in variable positions as discussed in the peritoneal chapter. One should never have an entrance point more posterior than the mid-axillary line—if a collection is small, it would be better to traverse an organ. On the right, one can penetrate the liver to approach such collections. I think this is preferable because with the liver abutting any such collections there are bacteria circulating through the liver anyway.

The left subphrenic space is demonstrated at this point; discussion of the right side is provided later under specific anatomic areas. When an abscess is present, it is best to choose one of the lowest levels of the abscess and to choose a point in the mid-axillary line (Fig. 61–105). The instrument is angled cephalad, the puncture made, and the wire advanced cephalad. Note how the wire naturally

moves cephalad and follows a line parallel to the intercostal spaces.

Several points should be made concerning the configuration and nature of the abscess collection. If an abscess collection is long, plan the trajectory of the puncture so that when the catheter is inserted it will lie throughout the length of the cavity. Two approaches may be used. First, one can choose an entrance site at the upper or lower end of the cavity (Fig. 61–105) so that the catheter will traverse the entire length or width. The alternative is to make two punctures at the center point, one directed cephalad and one directed caudad to permit positioning of a catheter at the top and bottom of the cavity (see section on catheterization) (Fig. 61–106). If such an abscess is elongated in a transverse direction, catheters should be similarly placed in that plane. If multiple septations are seen within a cavity, it is reasonable to plan the trajectory so that the maximum number of cavities will be traversed. Although best surgical results are obtained if an extraperitoneal approach is used, this is not true with percutaneous procedures. With surgery, a peritoneal approach is disadvantageous because it opens the possibility of “soiling” sterile portions of the peritoneum. A percutaneous puncture and drainage expose only the pathway to contamination rather than the wide surface of the peritoneum. Potential contamination is minimal if meticulous technique and methods are used.

Neither we nor other authors have found any indications that a peritoneal approach differs in outcome from an extraperitoneal approach with percutaneous drainage. In our experience, planning the trajectory to provide dependent drainage is not required. Purulent material follows the line of least resistance, which is the catheter tract. In fact, for subphrenic collections I prefer a more mid-axillary approach to a posterior one, to avoid the pleura.

Figure 61–104. A, CT scan shows fluid collection around the spleen. The needle is directed posteriorly and cephalad. B, With insertion of wire, the wire moves posterior and cephalad. C, With a digital radiograph, the cephalad positioning of the wire at the highest level of the abscess (arrow) below the diaphragm can be appreciated. There is no need to traverse the pleura to drain these very high collections.

Figure 61-105. A to D, The four scans taken before the drainage procedures show a long abscess in a child who had perforation of the duodenum secondary to a vasculitis. The abscess designated by the arrow is seen in the iliacus in A, the iliopsoas in B, the psoas in C, and the distal psoas in D. Others had attempted percutaneous drainage by only draining the fluid in D.

Selection of Modality

Once a trajectory has been planned, choose the guidance modality most suitable for the procedure. Fluoroscopy, ultrasound,^{193, 200,208} or CT can be used, but CT is the preferred method in almost all cases.^{111,147,192,203,389} The larger and more superficial fluid collections can be punctured by using fluoroscopy or ultrasound.^{338,359} The more difficult the abscess, that is, the deeper, smaller, or more critically located it is, the more likely it is that CT guidance can be used.

Diagnostic Aspiration

Before catheter or trocar placement, perform a diagnostic aspiration to confirm the presence of an abscess. There are two reasons I use an 18-gauge needle to perform diagnostic aspirations. First, the larger needle permits aspiration of even the thickest purulent material. Second, if at the time of aspiration the fluid appears purulent, the sheath permits insertion of an angiographic wire and catheter without a second puncture.

The actual puncture and placement of the needle are performed in the same manner as any other needle procedure. Try to plan the procedure so that the tip of the needle is placed in a more posterior or dependent location so that the anterior wall will not be retracted away from the needle as the fluid is aspirated and the wall partially collapses.

I take two steps to minimize the risk of contamination along the pathway. First, when draining abscesses in a solid

organ, I choose the path to include a “cuff” of normal parenchyma to lessen the chance of tearing the thin wall of an abscess. Second, at the time the puncture is made I aspirate a sufficient amount of material to lessen the “back pressure.” There is one reported case of spillage into the peritoneum that produced peritonitis, as well as a case of dissemination into the subphrenic area (Fig. 61-107) reported by Johnsen et al.¹⁹⁷ One must always strive for meticulous technique. If the catheter is in the area of the spillage, no further treatment is necessary, but if it is not, another catheter should be inserted in the area (Fig. 61-108).

If purulent material is aspirated, a sample of 10 to 20 mL is aspirated before catheter insertion and sent for culture. If the flow of purulent material is quite fast, I will remove 25 to 75 mL to relieve any back pressure and prevent any spillage or tracking during catheter insertion. After removal of this purulent material, I inject a small amount of urographic contrast material to facilitate the fluoroscopically guided catheter insertion. Also, if the wire and needle become inadvertently displaced, the contrast material permits a clear “target” for a puncture under fluoroscopy. Be careful not to inject too large a volume, which might overdilate the cavity and cause spillage of purulent material. After this step, insert an angiography wire into the cavity to stabilize the sheath if the patient is being transported to fluoroscopy. At times one may simply choose to insert the catheter on the CT, using the topogram as the method for confirming the catheter location or

Figure 61-105. *E to I*, The five images show the proper procedure with positioning of the catheter. In *E*, the needle puncture through the widest extent of the abscess was made. In *F*, the CT catheter (*vertical arrow*) is seen as it is used to perform a sonogram of the cavity that flows down through the psoas over the femoral head. The *horizontal arrow* shows the surgical catheter previously placed, which did not drain the abscess. In *G*, the wire and catheter were manipulated to follow the entire length of the cavity. In *H* and *I*, the axial scans show the upper and lower extent of the catheter in all portions of the abscess.

blindly using a sense of “feel.” Availability of a portable fluoroscopy device or an attached fluoroscope is helpful.

If the material is not obviously purulent, I aspirate only a small amount of fluid and send it for culture. In the event that a repeat puncture and drainage might be required, I try not to aspirate the fluid collection “dry”; if such a cavity is aspirated dry, there will be no well-defined lesion to target should a drainage be required later. I do not insert a catheter when the fluid is not obviously infected, because if such a collection is sterile, an indwelling catheter might introduce pyogens and cause a secondary infection. In

patients with tumors in the area, a cytologic sample should be sent to determine if there is a necrotic neoplasm or secondarily infected tumor giving toxic symptoms similar to abscesses (discussed later). Catheter drainage may provide some palliation for such tumors or secondarily infected tumors.

Catheter Selection and Insertion

There are two types of catheters available for drainage: drainage catheters inserted by the Seldinger method and

Figure 61-106. A, CT scan through the midabdomen shows a large abscess (A) in the retroperitoneum, containing some gas (arrow). B, The lowest portion of the abscess (A) extends into the pelvis behind the left adnexa of the uterus. C, Coronal reconstruction shows a long abscess (arrows) extending through the retroperitoneum. D, Plain film shows placement of two catheters entering from the middle of the cavity (curved arrow), extending to the top and bottom of the cavity (arrows).

Figure 61-107. CT scan shows an abscess in the left lobe filled with contrast material. The drainage catheter has penetrated the posterior surface of the liver; no repositioning was made because the catheter tracted through the cavity.

single-step catheters.^{128,143} Either may be chosen, depending on the specific nature of each case. The configuration of the tip and location of the holes vary among those available.

The size of the catheter and the size of the pigtail shape to be used should be matched to the size of the abscess cavity, so that the entire curved end is in the cavity. As a rule it is important to use the largest catheter possible from the beginning; if the procedure becomes technically difficult, one can settle for almost any size of catheter and upgrade it later. Larger catheters do permit faster drainage of material. It is important not to have holes outside the cavity. If holes are outside, leakage into a sterile space or organ can occur. Conversely, if a cavity is large, it may be important to cut additional side holes in the catheter if needed.

Two options are available for insertion of large abscess catheters. The trocar catheters now commercially available from many different companies can be used. I have found that these trocar catheters are useful for large, superficial abscesses but not so suitable for most of the small or critically located abscesses.

Figure 61-108. A, CT scan shows puncture of intrahepatic abscess (A) through a midaxillary line location. Because a cuff of normal liver was used, no leakage occurred at this time. B, After insertion of the large catheter (arrow), it was noted that a leakage of purulent material occurred into the subphrenic space (arrow). C, Puncture of the small subphrenic fluid was performed. When such punctures are attempted, they should be planned obliquely and so that the needle penetrates beyond the space. The instrument is withdrawn while suction is applied; the location of the tip in the space is heralded by aspiration of fluid. The wire and catheter are then inserted. D, Because of the small space, repeat scan is important to confirm the location of the catheter in the space (arrow).

The second option I also like to use is a two-step procedure. In the first step an angiographic catheter is inserted on the first day of the puncture and in the second step the catheter is upgraded in size on the second or third day as needed after the sinogram.

The chosen catheter can be inserted in one of two ways. First, if one has only limited experience, the best way is to transport the patient to a fluoroscopic unit for catheter insertion and positioning. If one has a fluoroscopic device with the CT scanner, as afforded by many companies,

placement of this catheter is quite easy. As a rule, I always adjust the catheter position to ensure that it traverses the entire length of the cavity and that there are no kinks. Also, if the cavity is small or if the catheter has a large number of holes, be certain that none of the holes are outside the cavity. If holes are outside the cavity, then dissemination can occur through the side hole with drainage or irrigation. The second choice is to put the catheter in by "feel" and to observe the location with the Topogram or the Scoutview. If one is quite experienced, this second

Figure 61-109. A, This scan shows a very large abscess, which is very wide across the entire abdomen. To ensure adequate drainage, a catheter was inserted from each side and crossed in the midline. B, This follow-up scan shows total evacuation of the cavity and the catheters in the midline.

method will suffice, and any necessary adjustment in catheter position can be done on the second or third day during the sinogram.

To ensure that the entire length of a cavity is covered, there are two possible approaches. One can start at either the highest or lowest end and then insert the catheter throughout the length. Alternatively, one can insert two separate catheters in the middle and cross them so that each one is directed toward the upper or lower extreme (Fig. 61-109). Cavities with multiple loculations may drain spontaneously, or the effective drainage can be improved with a fibrinolytic material as noted later. If there is any question about communication among the different spaces, one must not hesitate to use multiple catheters (Fig. 61-110).

With the catheter in place, I gently evacuate all of the purulent material from the cavity until the cavity is empty, unless several liters of material are present. In such cases it is probably prudent to remove no more than 1 L of fluid by aspiration and then to permit the remainder to drain

more slowly through the catheter. This prevents potential fluid shifts between various compartments. I adopted this approach after we had one patient who suffered a hypotensive collapse after the acute removal of 6 L of purulent material (Fig. 61-111). At this time I use saline irrigations to flush the cavity until the returning material is almost clear. If the fluid becomes blood tinged during the irrigation, I stop the irrigation and send the patient back to let the material drain slowly. Besides these steps of positioning and irrigation, I perform no other manipulation at the time of the first insertion to avoid bacteremia.

Some authors have recommended the use of a wire at this point to disrupt any septations or adhesions. This appears to be imprudent because use of a wire traumatizes the wall and may cause a significant bacteremia or hemorrhage from the granulation tissue.

Sinogram and Catheter Adjustment

Sinograms are performed somewhere between 48 and 72 hours subsequent to the procedure to check the position

Figure 61-110. A, Scan shows multiple, large abscess cavities in the liver. Because of the large number, only the two largest cavities were drained. B, Follow-up scan shows reduced size of two drained cavities as well as the other smaller cavities.

Figure 61-111. *A*, Large abscess cavity (arrows) with air-fluid level (curved arrow) is located in the left side of the abdomen. After the acute removal of 6 L of purulent material, this patient suffered a severe hypotensive crisis. *B*, Scan of the same patient after several days shows incorrect placement of the catheter (arrow) through the anterior wall of the abscess. The wall of the abscess (curved arrow) receded past the catheter so that holes in the catheter permitted air (open arrow) and material to flow into the peritoneum.

of the catheter and every 4 to 5 days after to assess the progress of healing. During the first sinogram one evaluates whether the catheter placed is still in correct position and is of adequate size for the evacuation of any residual purulent material. As the cavity is evacuated, the contour may change and shift the location of the catheter, requiring adjustment of the position. If there is considerable purulent material left, one may choose to increase the size of the catheter. At this time, sequential dilation may be performed safely. I discourage extensive dilation at the first procedure because of concerns about either spillage of bacteremia or bleeding. Furthermore, if the material is thick or loculations are present, one might institute catheter irrigation with fibrinolytic agents at this time, if it was not used initially.

If one chooses subsequent sinograms, they are used to assess the size of the cavity and the possible presence of fistula. Assessing the size of the cavity is important to determine the time of catheter removal. As healing occurs with the ingrowth of granulation tissue, the cavity size reduces. The catheter should be left in place until the cavity almost disappears. Fistulae are seldom seen except in the later sinograms as the inflammation recedes. Most fistulae close spontaneously (see later) (Fig. 61-112).

Catheter Management and Irrigation

Once the catheter is in place, a few guidelines must be followed to ensure a successful drainage. It has been my

Figure 61-112. *A*, CT scan shows two abscess cavities in the right side: one in the psoas muscle and one in the gluteus muscle behind the iliac crest. The high-density objects are cross-sections of two different catheters that were used to drain the abscesses. *B*, A sinogram taken later in the course of the patient's recovery shows communication of the long cavity in the psoas muscle with the small bowel. Total resolution without surgery followed (see text).

routine to leave a catheter only to gravity drainage. My concern about application of high suction is that the holes may be occluded by tissue and loculations can accumulate peripherally.

The one circumstance in which active suction is best is when there is free communication with either a fistula or biliary system (see Fig. 61-115).

Catheter irrigation should be performed with either one or two agents, as follows. The two agents we use to facilitate drainage are saline and tissue plasminogen activator (tPA). If the material being drained is quite thin and there are no definite septations noted on imaging studies, we inject saline. Saline in the amount of 10 to 15 mL should be injected every 6 to 8 hours to keep the catheter lumen clear. If the material being drained is quite thick or there are septations in the abscess, urokinase should be injected in amounts as follows, depending on the size of the cavity: 0 to 3 cm, 12,500 units; 3 to 5 cm, 25,000 units; 5 to 10 cm, 50,000 units; and greater than 10 cm, 100,000 units. After the urokinase has been injected, a small amount of saline should be used to clear the catheter of the urokinase. The catheter should be clamped for 5 minutes and then left to gravity drainage. The irrigations are continued for 3 to 4 days.

The effectiveness and safety of urokinase has been documented by our group⁸ in the literature (Fig. 61-113). Park et al³²⁰ showed that in vitro, the urokinase as compared with saline definitely decreased the viscosity of the purulent material (Fig. 61-114). The safety of urokinase in vivo was proved by Lahorra et al,²²⁴ who demonstrated that intracavitary urokinase produced no systemic effects. A later article by Haaga et al demonstrated considerable benefit for using urokinase compared to saline (Tables 61-8 to 61-10).

The action of urokinase is similar to tPA, which is why we now recommend using that agent. Both of these fibrinolytic agents change the substrate plasminogen to the active fibrinolytic agent plasmin. There is no reason to

Table 61-8. Other Abscess Parameters

suspect that its activity should be any different than urokinase. If one reviews the tables of information from the urokinase study, it can be seen that it improved the clinical factors of the patient and shortened the drainage time and hospital stay. This is an "off-label" use of the drug and so a patient must be notified of that, but it is legal for a physician to use the product in this fashion. In fact, we are now in the midst of an FDA-reviewed trial in which the FDA ruled there was no need for a new IND application. At this time the agent is not approved for usage, but individual physicians can use such drugs because they are approved for other uses.

Constant Irrigation

In some cases when especially thick material is present or there is injury to the vascular supply, placement of several catheters for irrigation may be beneficial. In such

Figure 61-113. A, CT scan shows large high-density mass (arrow) in the posterior pelvis. The mass proved to be an infected hematoma following hysterectomy. The patient had systemic lupus and was on high doses of systemic steroids. Even with these complicating factors, the patient was cured by percutaneous drainage enhanced by urokinase irrigations. B, Follow-up scan shows reduction in size of cavity with a high-density catheter in place. There was ultimately total resolution without surgical treatment.

CATHETER SIZE VERSUS TIME TO DRAIN
10 ML OF FLUID

Figure 61-114. An in vitro experiment was performed evaluating different parameters including urokinase treatment. The graph shows the drainage time of various fluid types through various sizes of catheters. The upper two lines show how urokinase improves the drainage of purulent material. (Data from Park JK, Kraus FC, Haaga JR: Fluid flow during percutaneous drainage procedures: An in vitro study of the effects of fluid viscosity, catheter size, and adjunctive urokinase. *AJR Am J Roentgenol* 160:165-169, 1993.)

cases one should make sure that fluid is moving freely between the catheters so there is no buildup of fluid (see later section on hepatic abscess drainage).

Follow-up Evaluation

Before final removal of the catheter in a routine case, perform a final CT scan to ensure that all areas of the

abscess are drained. An abscess that is completely resolved should show virtually complete obliteration of the cavity (but one may see a small amount of residual fluid and air) or decreased density in the liver. If a considerable amount of fluid remains, it is best to wait until the cavity has more completely resolved and has been reduced in size by granulation tissue. If a patient is doing well clinically, he or she may be discharged and managed as an outpatient during the time it takes for the cavity to granulate closed.

The last question to be considered during this final evaluation is whether the primary cause of the abscess and any important sequelae have been found. In most instances an abscess is the result of a surgical procedure or other intervention, but if there is no known cause, other diagnostic studies should be performed until all possible causes have been excluded (e.g., ulcer, diverticula). If a surgical problem exists, the appropriate therapy is instituted. In most instances a sinogram will have demonstrated a fistula to a loop of bowel, and management as described later is appropriate.

Catheter Removal

When a drainage procedure has gone well, the patient will respond quickly and show dramatic clinical improvement. In such patients the fever will defervesce, the white

blood cell count will drop, and sweating episodes will stop. The progress of the drainage can also be assessed by following the sequential changes in the physical appearance of the fluid. Initially, the material will be cloudy and turbid; it will then change to a serosanguineous appearance, and finally it will change to a clear serous material. Cultures of the fluid will also change sequentially so that when the abscess has resolved, drainage fluid will be sterile. After this clinical response and the change in character of the material, the catheter can be removed.

If the fluid from the catheter does not change as expected but drains bile or enteric contents, a repeat sinogram is necessary to evaluate for a fistula. Many times fistulae may not be seen with an early sinogram, since they will be closed because of edema and inflammation.

The decision to remove the catheter is quite easy if the course of the drainage (i.e., clinical response, evolution of fluid changes, and appearance of the sinograms) is as expected. Before removal of a catheter, a final scan should be obtained to ensure that the cavity has closed completely. If this has occurred and there is no continued drainage, the catheter can be removed. The patient's antibiotics should be continued for several days after removal of the catheter.

Fistulae

Gastrointestinal fistulae commonly occur with intra-abdominal abscesses; some probably are causative in nature, and some are sequelae. Management depends on the amount of flow, whether it is of low or high output.^{213, 229,292} Low-output fistulae (320 mL per day) usually close spontaneously without additional therapy (see Fig. 61–103). High-output fistulae require treatment. High suction on the catheter should be maintained, and the bowel should be put at rest. This usually means insertion of a nasogastric tube. Hyperalimentation may also be needed for several weeks in some severe cases. Failure of these methods indicates a need for surgery.

Drainage Issues

Drainage Errors

Relative to placement of the catheter, it is important that the largest catheter possible be inserted to permit reasonably rapid drainage of the fluid but also to provide ample

diameter should some purulent material become inspissated on the inner wall of the catheter. This does not mean that a massive catheter is required, but least a 10- to 12-French should be used. Also the catheter should be placed in the most remote site of the cavity so that loculations do not occur distal to the placement of the catheter.

The administration of antibiotics is absolutely mandatory. Historically, it has been widely recognized that drainage is even more critical than administration of antibiotics, but the facts are that abscesses resolve quicker and lessen the possibility of generalized sepsis, which is always possible.

Proper maintenance of the catheter includes irrigation of the catheter adequately with either saline or a fibrinolytic material. Purulent material tends to become encrusted within the lumen so the functional diameter is reduced. Catheters should be irrigated three times a day with saline, with a volume to clear the entire catheter volume. In many cases, a fibrinolytic should be used. Our study with a fibrinolytic clearly showed remarkable improvement in the resolution of abscesses using this agent. Septations and loculations are also cleared by such a fibrinolytic agent.

Although the routine abscess does not require suction, in some circumstances drainage is improved by its use. If a sinogram demonstrates a fistula to the biliary system or a loop of bowel, application of suction is mandatory. In these cases resolution will not occur unless suction is maintained to ensure the cavity and fistula are devoid of excess material (Fig. 61–115).

Finally, if an abscess does not resolve with drainage or even increases in size, one should suspect a fungal infection or even spontaneous bleeding. It is frequently observed that the infectious agent in an abscess may change based on elimination of sensitive organisms and selection of resistant organisms. *Candida* commonly becomes the dominant organism in a patient with multiorganism infection who is treated with broad-spectrum antibiotics selected for bacterial pyogens. In several cases, we have encountered an abscess that appeared to increase in size and developed an elevated density. In such cases, localized bleeding had occurred due to the infectious injury to local blood vessels (Fig. 61–116).

Errors associated with abscess drainages have been documented by numerous authors.^{109,111,140,141,225} Perhaps the most common error made is the improper choice of trajectory, which can cause either a portion of the pleura to be crossed when draining a subphrenic abscess or a solid

Figure 61-115. A, Scan shows a large abscess in anterior lower abdomen, with an air-fluid level (arrow) that did not resolve with siphon drainage. B, Application of suction was required, which resulted in total resolution. Note that the air-fluid level is resolved and no residual material is noted around the catheter.

organ to be traversed. Although with today's potent antibiotics dissemination of an infection is infrequent, it can occur and produce significant difficulty.

Other errors include selecting inappropriate cases—attempting to drain either an inflamed area that is not liquefied, an infected tumor, a fungal infection, or an infected hematoma. Infected hematomas cannot be drained using routine methods with saline or a catheter irrigant.

Several other common errors occur late in management. Inadvertent or early removal of the catheter results in recurrence of the abscess. Failure to either identify or correct the cause results in a recurrence such as fistula or ulcer. If a final CT scan is not obtained, a recurrent or undrained abscess can be present.

Unusual Clinical Circumstances

A number of unusual clinical circumstances are encountered in daily practice that are worthwhile to note specifi-

cally. These include patients with Crohn's disease, critically ill patients in intensive care, and infections caused by antibiotic-resistant organisms.

Relative to Crohn's disease, Garcia et al⁹⁹ reported on the outcome of medical/percutaneous drainage versus surgical treatment. In their series of 51 patients, fewer recurrent abscesses developed in postoperative patients than in those treated by the more conservative method (12% vs. 56%).

Schurawitzki et al³⁵² noted the superiority of CT guidance over ultrasound in the intensive care setting. With ultrasound there were a high number of equivocal studies that prevented adequate evaluation and/or performance of a drainage procedure.

Antibiotic-resistant organisms are becoming more prevalent in the environment, so the question of drainage effectiveness is raised. Catalano et al⁴⁹ reported a series of 21 patients with vancomycin-resistant enterococci abscesses.

Figure 61-116. A, Scan shows an abscess that appears to be draining appropriately. B, Subsequent scan shows enlargement of the abscess cavity (arrow) with increased density secondary to local bleeding.

In this group, 71% were drained successfully using standard guidance methods and systemic antibiotics.

Success Rates

Since the introduction and development of percutaneous abscess drainages, there has been controversy among the various groups about the achievable success rate, which overall has varied between 62% and 90%. The differences in success rates undoubtedly depend on numerous factors, including selection criteria, drainage techniques and catheters, and final criteria for outcome determination (i.e., definition of cure, palliation, etc).

A number of authors have studied the factors that affect the outcome of the drainage procedures. Several major determinants have been found, including the status of the immune system, the overall severity of the patient's illness, and the accuracy of abscess localization.

Lambiase²²⁹ recently reported a large series of patients treated with PAD and noted a significant difference in the outcomes of his patients (see earlier section on immune system). He found that those patients who were immunocompetent had a successful outcome in 72.6%, compared with those immunocompromised patients with a success rate of 53.4%.

Levison et al²³⁹ correlated the APACHE II score with drainage techniques and outcomes. He found that those patients with scores less than 15 had a mortality rate of 1.7% and those with scores greater than 15 had a mortality rate of 78%. There was no benefit of one method—surgical or percutaneous drainage—over the other.

Deveney et al⁷¹ studied the outcome of abscess drainage in two periods: the first in the 1970s and the second in the 1980s. The difference in mortality in the two periods was 39% compared with 21%, respectively. There was no difference in outcome between patients treated with surgical or those treated with percutaneous methods. The authors concluded that the improvement in localization had a major impact on the treatment of abscesses.

There are a number of reasons for the failures reported. These include premature withdrawal of the catheter, presence of a gastrointestinal fistula, pleural contamination, hemorrhage, and the errors of selecting cases as noted earlier.

Laing et al²²⁵ reported a series of 136 patients with a failure of 29 of 119 attempted curative procedures. With infected pancreatic processes the authors were successful in 11 of 22 cases. In their series they had 17 patients with identified gastrointestinal fistula; 9 resolved spontaneously, and 8 required surgical management. Failure to document the complete obliteration of abscesses by CT resulted in failure in 7 cases. The authors had two cases of hemorrhage associated with inappropriate placement of catheters in phlegmonous areas. The most common misdiagnosis was failure to identify loculated or residual cavities. Premature withdrawal was made in a number of cases because of the cessation of drainage fluid. The authors recommended that a repeat CT scan be performed before the removal of the catheter.

Complications

The incidence of complications varies widely, depending on technique, types of abscess being drained, and the various authors' experience. The reported rates vary between 5% and 9.8%. In regard to possible abscess locations, the complication rate varies between 1.4% and 30%. The lowest complication rate is associated with the liver and the highest with the spleen (see later section on specific location).

The most common complication in all series is that of sepsis immediately after the catheter insertion. According to our review of the literature, this occurred in about 6% of all cases; as seen in the recent review article by Lambiase,²³⁰ it occurred in about 4.2% of cases.

Other less frequent complications included spontaneous hemorrhage, spillage of infected material, and fistula formation.

Anatomic Approaches

The various anatomic areas involved by abscesses have unique characteristics as discussed in the earlier chapter on the peritoneum. Information unique to the technical approach and outcomes in each area will be discussed in the following sections.

Subphrenic Abscesses

With a subphrenic abscess, one must always look at the contiguous anatomic areas to see if there are any extensions of the abscess into these areas. Contiguous spaces that may require drainage include the right subhepatic and right pericolic space with right subphrenic abscesses. With left subphrenic abscesses, extension into the right subphrenic, left subhepatic, and the left pericolic space may also occur. Traditionally, such extension is not expected, but because of anatomic variability some peritoneal margins do not serve as effective barriers to the spread of infection.

When performing drainage procedures of the subphrenic spaces, several anatomic points should be kept in mind. To best avoid the pleural space, remember the attachment of the diaphragm. The slips of the diaphragm attach more cephalad anteriorly and more caudad posteriorly. Because of these relationships the entrance point for a drainage should not be more posterior than the midaxillary line (Figs. 61–117 and 61–118). The trajectory for such procedures should be from a caudad-to-cephalad angle. The target for entrance of the needle should be the lowest portion of the abscess. This permits positioning of the catheter throughout the enteric length and keeps the trajectory as far away from the diaphragm as possible, ensuring avoidance of the pleural space.

Obviously, when performing such a procedure, always visualize and avoid the pleural space, gallbladder, and hepatic flexure of colon when planning the trajectory. If there is any problem with localizing a subphrenic abscess or separating hepatic flexure of colon from the liver, place the patient in the left decubitus position.

The rate of cure for subphrenic collections varies be-

Figure 61-117. The pathway for needle puncture and catheter insertion should avoid the pleural space if at all possible. Because the pleural space is deeper posteriorly, a more anterior approach facilitates the avoidance of the pleural space. *A*, Axial scan shows the needle (*arrow*) being inserted anterior adjacent to the anterior slip of diaphragm. *B*, Higher scan shows the needle tip in the abscess cavity. Note how the pleural space has been avoided. *C*, Topogram shows radiographic type of image demonstrating catheter in right.

tween 79% and 81%. Complications include empyema and sepsis, the incidence of which is 2%.^{111,147,230,295}

Right Subhepatic Abscess

An abscess in the right subhepatic space can be easily approached either laterally or posterolaterally. Penetration of any adjacent structure such as the colon, gallbladder, or duodenum can be easily avoided. In some cases a left decubitus position can also be helpful in moving the hepatic flexure of the colon to simplify a puncture (Fig. 61-119). In cases when clear access is not available, it is reasonable to traverse a portion of the liver. Obviously, the liver in such cases is clearly exposed to the pyogens because of close proximity so there is minimal risk with this alternative trajectory.

Left Subhepatic Abscess

This abscess, located in the anterior subphrenic space below the left lobe of the liver, appears between the liver and the stomach on axial CT scan. The administration of oral contrast is important for confirmation of the stomach location. The optimal approach for this area is a directly anterior approach that avoids liver and stomach (Fig. 61-120).

Omental Bursa

Drainage of the omental bursa can be approached from several directions. Fluid collections in the inferior recess of the lesser sac can be approached anteriorly beneath the lower margin of the stomach if a fluid collection is large enough. If the fluid collection is in the splenic portion

Figure 61-118. A, Large subdiaphragmatic abscess extends as far posteriorly as the coronary ligaments. This proved to be a *Candida* abscess. B, CT scan during a guided puncture of the fluid collection, from a more anterior approach. The more anterior the approach for such collections the better, because the diaphragm is higher anteriorly than posteriorly. Use of a catheter irrigant is important. The abscess was successfully drained. C, Radiograph shows a larger catheter that was inserted into the cavity. The best flow of purulent material is achieved with large-bore catheters and the use of a fibrinolytic agent (see text).

Figure 61-119. A, CT scan of a patient in the supine position shows a high-density fluid collection in the right subhepatic space. B, When the patient is positioned on the left side, the fluid remains in the same location and does not shift. Note the drainage needle in the right flank.

Figure 61-120. Collections in the left subhepatic space are best approached through the gastrohepatic space. The needle (*arrow*) will usually avoid liver and stomach; if inadvertent puncture occurs on occasion, it is certainly better than intentionally penetrating these structures in every case. *B*, Scan shows wire and catheter (*arrow*) coiled in abscess.

of the inferior recess, the best approach is through the gastrosplenic ligament. This approach is best accomplished when the patient is in a right decubitus position to permit the stomach to shift anteriorly. Obviously, in such cases one must be careful to avoid the splenic flexure of the

colon, looking carefully for varices in the gastrosplenic ligament to avoid penetration of any such vessels (Figs. 61-121 and 61-122).

If the approach through the gastrosplenic ligament is not available, two other approaches are possible. For a

Figure 61-121. *A*, Scan shows the standard approach for drainage of the superior recess of less sac behind the stomach (*S*). The space is wide enough between the stomach and spleen to permit easy access. *B*, Radiograph shows catheter in splenic recess of lesser sac.

Figure 61-122. A, Drainage of the splenic recess of the lesser bursa, behind the stomach (S) was not possible with the patient in the supine position. B, With the patient lying in the right decubitus position, the stomach (S) moved anteriorly, providing a wide pathway between the spleen and stomach (arrows). C, Insertion of the catheter (arrow) through the space was easily accomplished.

second choice I would use a transgastric approach, ideally through a PEG as described earlier for pseudocysts. Another approach is a transhepatic approach through the left lobe of the liver (other authors recommend this as a primary approach).²⁹³ I dislike this approach because of possible injury or pyogenic dissemination into the left biliary or portal system.

Inferior Recess of Lesser Bursa and Porta Region

With the mastery of these techniques it is now possible to approach drainage of deep areas, which can provide remarkable benefit. These deep areas are difficult to drain by inexperienced operators, but with experience and knowledge of the techniques described in this chapter, drainage of very deep areas is possible. To successfully accomplish these procedures one must take advantage of patient posi-

tioning and also needle deflection as described in earlier sections (Figs. 61-123 and 61-124).

Pericolic Spaces

The pericolic spaces are easily approached laterally. One should always look for extension of an abscess into the pelvis or either subphrenic space. Contrary to traditional teaching, an abscess in the left pericolic space may extend into the left subphrenic space unimpeded by the phrenicocolic ligament.

When draining an abscess in these spaces, always make sure the catheter traverses the entire length of the cavity. To do this it is always best to enter either the upper or lower end of the cavity. Another option is to insert two catheters at the midportion of the cavity, with one extending cephalad and one extending caudad.

Figure 61-123. A, A patient with a small abscess (vertical arrow) beside a metallic stent in the biliary system (horizontal arrow) anterior to the vena cava (C). An anterior approach would be impossible, so a posterior approach was chosen. For the needle to clear the vena cava, the bevel was rotated toward the left (vena cava) and pushed slowly to permit deflection. B, Placement of the needle precisely in the abscess was accomplished. C, Final placement of the catheter (arrows) next to the stent (small arrows) was accomplished. Patient defervesced and survived, without surgical drainage.

Figure 61-124. A, The patient was positioned in the lateral position to permit access through the lateral abdomen to reach the small abscess (arrow) beside the opaque biliary stent. The needle was advanced past the kidney by turning the bevel toward the kidney and pushing slowly. B, Scan shows placement of the needle in the cavity with contrast injection (arrow). C, Final scan before catheter removal shows resolution of the abscess. The abscess was caused by a small diverticular abscess.

Empyema and Pleural Effusions

Drainage of empyemas is quite straightforward, and the same methods are used as other areas. The most important point relative to empyemas is to use a more lateral or anterior approach in preference to a posterior approach. If a catheter is inserted posteriorly, it is uncomfortable for the patient, and the tube is likely to kink and limit the drainage. Because such abscesses have a significant amount of inflammatory reaction, vacuum on the catheter is required not to keep the lung re-expanded but rather to improve removal of the material.

If a pleural effusion is being drained, it is best to have the catheter put to a water-seal vacuum drainage to prevent a pneumothorax from forming.

Liver Abscesses

Abscesses in the liver should be approached by the shortest trajectory available, with an entrance point on the anterior or lateral surface. When a lateral entrance site is used, do not go more posterior than the midaxillary line, to avoid traversing the pleura.

When puncturing and draining hepatic abscess, avoid any visible hepatic vessel as well as the gallbladder and pleura. Also, when planning the trajectory for hepatic abscesses, always include a cuff of normal tissue to prevent inadvertent spillage of material into the peritoneum.

Many hepatic abscesses may appear to be multiseptated,^{74,76,197} but experience has shown that many clear completely with one drainage tube. A variety of explanations have been proposed, including (1) they intercommunicate, (2) they drain spontaneously into the drained cavity, and (3) antibiotics clear the different cavities. A repeat scan is important to ensure that all such cavities eventually clear because separate cavities that persist occasionally require drainage (Figs. 61-110 and 61-125).

The success rate for hepatic abscesses varies between 69% and 89%.^{177,197} The complication rate varies between 1.7% and 7.3%. The complications include sepsis, contamination of peritoneum, and production of an empyema.

Renal Abscesses

Such abscesses are best approached posteriorly through a path avoiding erector spinal muscles, colon, liver, and spleen. The puncture and drainage of most such abscesses can be performed with ultrasound or CT guidance. When the upper pole is involved, CT is indicated to avoid inadvertent trauma to the spleen, splenic pedicle, or pancreas. Success rate varies (Fig. 61-126).

Splenic Abscess

Drainage of splenic abscess is quite controversial for several reasons. Some early investigators reported favorably on drainage of splenic abscesses, but if one carefully reviews their reports, there was a high incidence of emer-

Figure 61-125. Two large abscesses in a patient with liver transplant. Because the portal vein was occluded, the tissue was necrotic and effective drainage was difficult. Two catheters were inserted, with one providing inflow and the second providing exit flow from the communicating cavities.

Figure 61-126. A, CT scan shows a large abscess around the left kidney and severe pyohydronephrosis. The needle trajectory was planned to cross both abscess collections. B, Catheter injection shows opacification of the collecting system and some extravasation of contrast material into the perinephric space.

gent splenectomy. Having never been an advocate of such procedures on a routine basis, we have waited for additional experience to be accumulated before recommending this approach.

Unfortunately the recent information has remained inconsistent. Liu et al²⁴⁴ reported a 90% success rate, whereas Green¹²³ reported a 25% success rate. These reports come from different areas of the world, and there may well be differences in selection of the patients as well as geographic and ethnic differences among the patients.

Because the incidence of splenic abscesses worldwide is increasing due to the increasing number of immunocompromised patients, I believe the procedure be used but only in very selected patients. Because the spleen is so vascular, one should probably drain only those abscesses that are very close to the surface of the spleen. Realizing this procedure has not proven to be safe in controlled studies, one must always have close communication with surgeons to make sure an emergent splenectomy is possible.

Perirenal and Pararenal Spaces

The anterior and posterior pararenal spaces are frequent sites of abscess and can be approached safely; however, certain facts must be remembered. These spaces extend from the pelvis to the diaphragm and are long. Unless a catheter or catheters are positioned throughout the entire length of the cavity, drainage may not be successful (Fig. 61-127). It is especially important to use CT for follow-up of such cases because the abscesses may spread toward the diaphragm or pelvis. Examination of these areas may be difficult with ultrasound.

The success rate for these abscesses varies between 68% and 81%. The complication rate varies between 3% and 6%, with sepsis and hemorrhage being the most common.^{227,230}

Pelvic Abscesses

The procedure for drainage of pelvic abscesses is quite similar to that of other areas. The most significant controversy involves the choice of drainage pathways. It is our

opinion that the best pathways are an anterior, lateral, or transrectal one (Figs. 61-128 and 61-129).

When such abscess cavities are close to the rectum, a transrectal approach is indicated¹⁰³ (Figs. 61-130 and 61-131). To perform this procedure, a series of baseline scans are taken over the pelvis to demonstrate the collection. A short plastic tube (with Betadine ointment) is then inserted into the rectum. A plastic sheath needle is inserted into the tube and a series of repeat scans are taken over the pelvis. Once the needle is aligned properly, the puncture into the fluid collection is made. The needle is removed, but the plastic tube is left in place to serve as a conduit for catheter insertion. The tube prevents buckling of the wire or catheter in the rectum during the insertion.

The last choice for draining pelvic abscesses is through the sciatic notch (Fig. 61-132). This pathway is satisfactory for biopsy procedures, but long-term drainage catheters are not recommended, for two reasons. The use of this pathway can produce a lot of pain, and there have been reports of abscess tracking into the gluteal muscles, of sciatic neuritis, and of pseudoaneurysm formation in the iliac vessels.

Controversial Areas

Treatment Without Catheter Drainage

Several authors have reported on the concept of treating abscesses with only aspiration and lavage of an abscess cavity and intravenous antibiotics. The largest series reported by Wroblecka and Kuligowska⁴¹¹ involved 82 non-consecutive patients. These authors used a single-step procedure in which they used an 18-gauge needle to puncture, aspirate purulent material, and irrigate with saline. They claim a 90% cure rate in unilocular abscess and a 85% cure rate in multiloculated abscesses.

When reviewing these articles, it must be noted these were not well-designed studies. They did not have well-defined selection criteria, were nonconsecutive, and had no control groups. The data are subject to remarkable bias because of selection of patients.

From my perspective, I have no intention of using this

Figure 61-127. A, Scan shows a fluid collection around the left kidney, representing a perinephric abscess. B, Placement of the catheter into the abscess was performed through the posterior flank.

approach until further controlled studies are performed. I do find the concept interesting and believe there may be some limited role in the future if the method can be better defined and results proven. In the future such an approach might be effective if a long-acting antibiotic could be deposited in the abscess cavity.

Catheters

Some authors use angiographic catheters, whereas others use large catheters and trocars. In most areas either type of

Figure 61-128. A, Scan shows an approach to an abscess (A) posterior to the bladder and adjacent to sigmoid colon (arrow) from diverticular abscess. B, Scan shows insertion of a wire throughout the length of the cavity. C, Radiograph shows the injection of contrast material, demonstrating a fistula to diverticulum of colon.

catheter works well, except in the case of certain pancreatic abscesses (see later section). In pertinent drainage literature, a report by Park et al³²⁰ showed there was little difference in drainage success rates regardless of whether small or large catheters were used. This is probably the result of selection of catheters by operators (i.e., small catheters for thin material and large catheters for thick material). Controversy exists about whether gravity (siphon) drainage, sump drainage, or irrigation drainage (multiple catheters) is the most effective. There is no clear advantage to any of these methods appearing in the surgical and radiologic literature, so any individual preference can be followed.

Figure 61-129. Access (arrow) to an abscess caused by a ruptured appendix was possible by positioning the patient in the oblique position. The needle was targeted to the appendicolith (oblique arrow) in case extraction of calculus was indicated.

Sinograms

Some authors^{147,225,230} have performed sinograms to follow abscess cavities, whereas others¹¹¹ have not. We use sinograms in many cases to follow the progress of granulation tissue that closes the cavity. Sinograms are not intended to see “undrained” areas. By definition, if these areas are not drained and do not communicate, one will not see them. Sinograms are used to see the size of the cavity as it heals from granulation or to detect fistulae. CT scanning is used to see undrained areas. With this in mind, one must not overinject cavities during sinograms to maximum distention, because this can cause spillage or bacteria into anatomic spaces or into blood or other portions of the organ.

Antibiotics

It is my belief that all patients who have a percutaneous procedure should have systemic antibiotics before¹⁰⁰ and during the course of abscess drainage.

With antibiotics, patients have quicker resolution of the abscess and fewer local complications. I have noted that some patients not receiving antibiotics may develop a localized cellulitis around the site of catheter insertion; administration of antibiotics resolves or prevents this. If antibiotics are not given, septicemia is more likely to occur after or during instrument manipulation.

In our opinion the only valid controversy is whether the antibiotics should be started before or after the diagnostic aspiration. Starting antibiotics when a patient initially develops septic symptoms can be justified to prevent further deterioration. On the other hand, it can be argued that unless the patient is not receiving antibiotics, a valid culture cannot be obtained. It appears that either philosophy is sound; I usually accept the preference expressed by my clinical colleagues attending the patient.

Mucolytic Agents

There have been several suggestions in the literature about using materials to try to enhance drainage from abscesses. One author³⁹¹ has proposed the use of acetylcysteine (Mucomyst) to decrease the viscosity of purulent material; most workers do not accept this material as being effective.

Fibrinolytic Agents

Extensive work has been performed using urokinase, but unfortunately that agent has been taken from the marketplace. Because fibrinolytic agents all work by the same pathway, converting plasminogen to plasmin, the newer agents, prourokinase and tPA, should both be useful in a similar fashion. Because no work has yet been done on those agents, one would need to calculate equivalent doses of these agents if a fibrinolytic is needed. Reviewing the

Figure 61-130. A, The various devices used for a transrectal approach include the plastic sheath needle, plastic cannula, angiographic wire, and catheter. B, Simulated procedure using the bony pelvis of a skeleton and the equipment as noted in A. This shows the plastic sheath along the side of the finger. The needle is within the sheath (protecting both the rectum and the operator's finger), and Betadine ointment occludes the end of the plastic sheath.

Figure 61-131. *A*, CT scan shows a large abscess between the uterus and rectum, which was drained by a transrectal drainage. *B*, Topogram shows a needle being inserted by means of the rectum, through the plastic tube as noted in Figure 61-131. *C*, CT scan over the lower pelvis shows the needle in the rectum. Compared with the first image in *A*, the needle was correctly angled to enter the cavity. *D*, Lowest CT scan over the pelvis shows the needle entering the abscess cavity. With the use of the topogram, the angiographic wire and catheter were inserted.

Figure 61-132. *A*, CT scan of the pelvis shows a large abscess posterior to the bladder and anterior to the rectum. *B*, Follow-up scan shows catheter drainage through the sciatic notch. Note that the cavity is much smaller, but there is also an abscess that has tracked posteriorly into the gluteal muscle.

clinical data on urokinase is helpful in this regard.^{224,235,320} In an article by our group, Park et al³²⁰ showed that in vitro urokinase decreased the viscosity of purulent material by 23%. Increased flow through various catheters was observed, and this was most significant with small-caliber catheters.

In another report by our group, Lahorra et al²²⁴ showed the safety of administering urokinase through drainage catheters into abscess cavities. In this study all abscesses with loculations were successfully drained, as well as three infected hematomas, one fungal abscess, and one recurrent abscess. Based on this initial experience, we now routinely use fibrinolytics in any abscess that contains thick material or infected hematoma (Fig. 61–133). See the previous section on fibrinolytics, under “Catheter Management.” Our most recent article on urokinase showed its use improved treatment of abscesses. Its use produced improvement of clinical parameters earlier and shortened hospital stay. Other fibrinolytics are now being evaluated as irrigant for catheters.

Palliative Procedures

A number of authors have advocated palliative drainage procedures in different areas. PAD in each of these areas has been tried with varying success (each area is described in the following sections).

Drainage of Splenic Abscesses. Percutaneous drainage of splenic abscess is a questionable procedure because of surgical experience and the reported data in the literature. The spleen is a large vascular organ, and any manipulation presents a potential risk. Even with the current surgical trends favoring preservation of the spleen in traumatic injury, most surgeons perform a splenectomy rather than attempt a catheter drainage. In the accumulated literature about percutaneous abscess drainage of the spleen, a high failure rate, as well as high complication and mortality rates are reported. I believe that surgery is the most acceptable treatment for a splenic abscess, except in extraordinary cases (Fig. 61–133).

Drainage of Pancreatic Abscesses. Drainage of pancreatic abscess by PAD is a complex issue that has not yet been resolved, but certain comments can be made. The issue is complex because there is a discrepancy in the literature about the objective results, recommendations, and the experience of various authors.

The overall success rate is 57%, with a fairly high complication rate. Complications have been both short- and long-term. Short-term complications have been related to hemorrhage, either for pseudoaneurysms or for inappropriately attempted drainage of poorly defined phlegmons. Initial attempts to drain pancreatic abscesses were somewhat nonselective, and the methods were not clearly defined. Recent personal communications have reported that better selection criteria and more clearly defined methods are being used (see Fig. 61–134).

Most workers differentiate between necrotic, ill-defined pancreatitis with superimposed infection versus well-delineated, low-density fluid collections, which more closely resemble infected pseudocysts.

The latter types of infections, the well-defined fluid

Figure 61–133. Small splenic abscess in the anterior spleen caused by *Salmonella*. This abscess, despite having been previously aspirated, drained by catheter, and treated with antibiotics, continued to recur. Catheter drainage of the abscess was performed because it had been done before without difficulty and because the patient refused surgery. Redrainage with urokinase as an irrigant produced total resolution.

Figure 61–134. A, CT scan shows a large catheter in the large pancreatic abscess. B, Radiograph shows a catheter inserted into the abscess.

density collections, are those that are best suited for percutaneous drainage. The standard methods using the Seldinger technique or the trocar methods provide good results. Freeny^{95,96} reported a high success rate with such methods. In his group of 21 patients, the success rate was 85%. Von Sonnenberg^{384,386-390} also claimed a high success rate of 69%. They encountered 13 fistulae, 10 of which closed spontaneously. Most recently, Lambiase²²⁹⁻²³¹ reported successful drainage of 2 of 2 infected pseudocysts as compared with 1 of 7 cures in a group of patients with abscesses exclusive of pseudocysts.

The only worker attempting drainage of necrotic pancreatitis is Dr. Eric Martin.²⁶³ Employing what I would call extraordinary methods, he uses 20- to 30-French catheters, which are capable of draining large amounts of necrotic tissue. With these methods, he has success, complication, and mortality rates comparable to surgical results. In his group of 20 cases Martin had a cure rate of 65%, a mortality rate of 25%, and fistulae in 10% of cases. Although these values seem high, one should remember this is treatment of infected necrotic pancreatitis, not well-defined fluid collections.

Regardless of the primary approach taken for drainage of pancreatic abscesses, the successful resolution of the problem depends on diligent, repetitive clinical and imaging evaluation of the patient. Close cooperation between surgeon and radiologist is quite essential because of the recurring and unpredictable nature of the disease. Many times, a radiologic procedure is needed after an operative drainage or vice versa to produce complete resolution of the problem. As has been indicated by Martin and others,²⁶⁴ regardless of optimal care a high percentage of such patients will die.

In my experience, the technique and approach used depend on the appearance and location of the pancreatic fluid collections. For well-defined collections, I am quite willing to perform percutaneous drainage because of the high success rate. Those collections representing infected necrotic tissue or poorly defined multiple collections are best drained surgically. If a patient has had a surgical drainage and develops a collection postoperatively, I will attempt percutaneous drainage regardless of the appearance, knowing that the infection is most likely well-confined and that a second surgical procedure would be quite difficult.

I use either an anatomic approach that avoids all adjacent organs or a transgastric approach. If one is attempting to avoid bowel or solid organs, the approach often must be retroperitoneal, anterior to the kidney or directly anterior. I use such a direct anterior approach only if there is a "window" between the various loops of bowel. If there is any problem with access, I choose a transgastric approach using the same method I have described for pseudocyst drainage, with a gastrostomy as a conduit for entry (see earlier section).

Diverticular Abscesses. Percutaneous drainage of diverticular abscesses is a technically simple procedure for which the indications are limited. The indications for this procedure are limited because in most patients with diverticular abscesses, a colonic diverticular fistula will result after successful drainage of the abscess. I concur with

Mueller et al,²⁹² who reported that the primary purpose in performing this procedure is to change a potential two-stage procedure into a one-stage procedure. Specifically, most cases of small diverticular abscesses can be treated with a single surgical procedure consisting of an en bloc resection of a segment of the sigmoid colon and a confined abscess. The entire problem is resolved with a single procedure. In those cases in which the abscess is so large that this cannot be accomplished, surgical treatment would require two procedures: one to drain the abscess and divert the bowel and a second to reanastomose the bowel. In such cases percutaneous drainage can remove the infectious material and a single surgical procedure can be performed to remove the offending segment of sigmoid colon (Fig. 61-128).

I try to approach such lesions from an angle not traversing bowel; I believe that including the bowel within the pathway increases the possibility of fistulae.

Neff reported a series of 16 patients with diverticular abscesses.³⁰¹ According to the author, all responded. In this group, 11 patients required sigmoid resection after the drainage and 1 patient had a three-stage procedure. There were 10 fistulae resulting; 2 required surgical treatment.

Infected Neoplasms. Although experience has shown that percutaneous drainage of infected neoplasms will not be curative,^{297,407} there has been some recent interest in using percutaneous drainage as a palliative procedure. Using the standard technique as described, Zeman⁴¹⁷ has had some positive experience with palliation. In 12 patients with infected tumors, those authors had noted improvement in all cases, with favorable response in 50%; no complications occurred.

Echinococcal Drainage

A number of authors (Bosanac and Lisanin,³³ Sayek and Onat,³⁵¹ Giorgio et al,¹¹⁵ Ormeci et al³¹³ and Khuroo et al²¹⁵) have reported on the percutaneous drainage of echinococcal cysts. The method is quite simple and consists of the typical percutaneous puncture and aspiration using ultrasound or CT. With the Seldinger technique, catheters between 12 and 20 French are inserted. The cavity is then irrigated with alcohol and Betadine and left in site for 30 minutes. The catheter is left to drainage until fluid ceases. Concurrent treatment with albendazole is also important, in the appropriate doses and duration. Anaphylactoid reactions did occur in several cases but were not fatal.

Amebic Abscess

Typically amebic abscesses respond to systemic treatment with amebicidal therapy; however in some cases the abscesses are resistant to drug therapy. Akgun et al,⁵ Tandon et al,³⁷⁷ and Hanna et al¹⁶⁵ reported on the use of aspiration and drainage in conjunction with aspiration and drainage. It was the consensus that percutaneous aspiration and drainage may expedite therapy and provide a cure when there is resistance to medical therapy.

Percutaneous Nephrostomy

The same advantages for CT procedures are applicable to nephrostomy placements, but several different points

should be emphasized. CT has been successful in a high percentage of cases; in one early report we completed 12 of 13 attempts.¹⁴⁸ Barbaric et al¹⁷ reported a series of 148 procedures using CT and fluoroscopy. Their success rate was 97% and there were no major complications. Authors such as Hagspiel et al¹⁶¹ and Merkle et al²⁷³ have used MRI for placement of nephrostomy tubes.

The indication for CT guidance is limited, but I believe that most nephrostomies can be performed easily using either fluoroscopic or ultrasonic guidance. Those cases for which we use CT guidance are renal transplants, unilateral kidney, high-risk patients, or a kidney with a urinoma associated with the hydronephrosis.

Renal transplants are well suited for CT nephrostomies. Transplants represent high-risk patients who are immunosuppressed, and therefore a higher margin of safety is needed. The transplants are somewhat mobile and the axis is unpredictable. CT may be needed to ensure proper placement of the catheter through the parenchyma. Unilateral kidneys should be performed with CT because these cases present a high-risk situation. Potential damage or complications in such cases must be minimized.

When a collecting system with hydronephrosis has ruptured and produced an adjacent urinoma, CT is better than other methods for several reasons. First, if the urinoma is displacing the axis of the kidney, the orientation can be appreciated. Second, if there is active excretion of contrast material, the perinephric space may fill with contrast material, making it difficult to visualize the collection system under fluoroscopy. This is not the case with CT (Fig. 61-135).

The technique is similar to that described for abscess punctures. Prepare the skin with the standard antiseptic preparation and administer a local anesthetic. Use an 18-

Figure 61-135. Scan shows percutaneous nephrostomy of a unilateral kidney. The needle is positioned in the dilated, contrast-filled pelvis (P). Note the small amount of contrast material that extravasated anteriorly from a small penetration of the anterior wall during the adjustment of the needle. Such small leaks are of no consequence if the collecting system is adequately drained.

Figure 61-136. CT-guided procedure of the author's daughter (see Dedication), who had multiple renal calculi. There is one catheter in the right kidney, and this shows puncture of the left kidney with the needle (arrow). Such special cases warrant the best method available.

gauge plastic-sheathed needle to puncture the renal pelvis. Insert an angiographic wire, remove the plastic sheath, and follow with the chosen nephrostomy catheter. The longitudinal type of scan or fluoroscopy may be used after the puncture to insert the catheter.

When the nephrostomy is performed under CT, several technical maneuvers are important. Once the collecting system has been penetrated, a small sample of fluid should be aspirated for culture and then a small amount of contrast material should be immediately injected. This injected contrast material permits direct visualization under fluoroscopy when the catheter is being inserted. In addition, I recommended the 18-gauge Teflon-sheathed needle so that with successful puncture the angiographic wire can be inserted into the collecting system without additional manipulation (Fig. 61-136). The patient can then be transported to the fluoroscopy area without concern about displacement of the sheath or wire. In some cases the final positioning of the catheter should be made under fluoroscopy, but in many cases adjustments can be made with localizing scans. If one has access to a fluoroscope attached to a CT scanner, this step is simplified.

Nerve Blocks

One of the newest and most exciting areas of interventional radiology is CT-guided nerve blocks. The same types of nerve blocks that were previously performed blindly or by fluoroscopy can be better performed with CT guidance.*

Celiac Nerve Blocks

It is important to review the rationale behind celiac nerve blocks to gain a better understanding of the process, side effects, and possible complications.

The sensory nerve fibers transmitting pain sensation

*References 43, 139, 151, 156, 158, 242, 285, 290.

from the bowel, mesentery, capsule of the liver, and some portions of the retroperitoneum around the major vessels pass through a major neural plexus adjacent to the celiac artery called the *celiac plexus*. This large plexus contains ganglia from the sympathetic, parasympathetic, and sensory nerves. Once the sensory fibers pass through this area, they converge to form the right and left splanchnic nerves through the retroperitoneum and the mediastinum toward the central nervous system.

Interruption of these sensory fibers prevents pain stimuli from being carried back to the brain, thereby eliminating pain. Numerous methods have been used to interrupt these pathways, including surgical ablation, unguided percutaneous neurolysis, and guided percutaneous neurolysis.

Before CT guidance, authors had tried fluoroscopic guidance and ultrasonic guidance, but most procedures were performed blind. These guidance methods have various supporters, depending on the experience at various institutions and the expertise of the individuals. These factors are of course quite variable; thus, some centers have excellent results and others have poor results with a high incidence of complications.

Unfortunately, because the different nerves cannot be separated from one another, ablation of the sensory fibers in turn produces ablation of both the sympathetic and parasympathetic fibers. This results in the two commonly observed side effects:

1. Short-term orthostatic hypotension produced by splanchnic pooling of blood, caused by interruption of the sympathetic fibers
2. Diarrhea from interruption of the parasympathetic fibers

Different Approaches

Three general methods have traditionally been used, a transcrural approach, a retrocrural approach, or an anterior approach. The retrocrural approach attempts to interrupt the pathway after the splanchnic nerves have formed and as the nerves course in the posterior mediastinum. The transcrural approach interrupts the pathway at the plexus before formation of the nerves. With our method I approach the plexus directly and use an angled trajectory so that the entire needle pathway is beneath the diaphragm. This lessens possible complications caused by tracking of medication into the chest or abdomen. Other authors have used an anterior approach to destroy the **plexus**.^{255,340}

Recommended Method

As with most CT procedures, my experience is quite extensive and dates back to the first such CT procedure in 1977¹⁵⁶ (Fig. 61-137). Since then I have evolved the technique to its current state.

The major elements of my technique are the following:

1. Use of a 19-gauge needle with 18-gauge Teflon sheath
2. Substitution of air instead of urographic contrast as a marker
3. Using a local anesthesia for a test block
4. Injection of 90% ethyl alcohol on the left side or bilaterally (Fig. 61-138), if needed

Figure 61-137. This CT procedure, which took place in 1976, shows the placement of two skinny needles for performance of a celiac nerve block (see text).

The early procedures reported by my group and Buy et al⁴³ used the 22-gauge skinny needles for the instruments and urographic contrast material mixed with alcohol for a marker. I have discarded the use of the skinny needles because they required too much pressure for injection. Since the pressure for injection is so high, any tissue resistance during injection cannot be manually perceived. According to the anesthesia literature, this ability to feel this pressure is important, because if excessive pressure is required, the needle may be inappropriately within the fascia of a vessel or organ.

In addition, the small-caliber needle that was previously used does not always permit free backflow of blood from a small vessel (as does the larger caliber 18-gauge sheath). Inappropriate injection into an artery can cause serious side effects, ranging from loss of an organ to paraplegia.

The injection of the local anesthetic is worthwhile for several reasons. First, there can be congenital variation in the location of the plexus. Depending on the relief of the abdominal pain with the local anesthetic, one can confirm that the pain sensed by the patient is carried by fibers through the plexus. If the pain is not relieved, it does not make sense to inject the alcohol, which can have significant complications.

Finally, instead of mixing contrast material with alcohol, we substitute 4 cc of ambient air to serve as a marker for injection. Because air works as well as contrast material, I decided that we should avoid any possible idiosyncratic contrast reactions or volume dilution of the alcohol.

Anatomic Approach

I use a posterior angled transcrural approach, which avoids virtually all anatomic structures. I do not penetrate the kidney, bowel, or other organs, because I believe that the terrible complications previously reported by the blind method were the result of inadvertent injection of a neurolytic agent into such structures. I attempt to interrupt the nerve fibers in the plexus itself primarily by placing the needles and the medication anterior to the aorta between

Figure 61-138. A, The equipment used for nerve blocks include a plastic sheath needle (sheath, needle, and stylet are disassembled), lidocaine anesthesia, and ethanol. B, This and the subsequent CT scan shows the appropriate positioning for a celiac nerve block. This scan shows the introduction of the needle into the retroperitoneum on the left. C, With cephalad angulation, the needle is passed behind the renal pedicle and then passed beside the aorta. D, This scan shows final placement of the needle tip beside the superior mesenteric artery behind the pancreas. One should note that even if inadvertent penetration of the vessels should occur, any adverse developments are unlikely (see text under other methods as proposed by Lieberman).

the superior mesenteric artery and the celiac artery. On some occasions interruption of the splanchnic nerves in the more peripheral areas must be accepted if the needles and medication are to be safely placed only posterior and lateral to the vessels.

I have not used the anterior approach or transaortic approach proposed by some because of concern about potential damage to the portal vein, hepatic artery, or pancreas.^{255,340}

Technique

The technique that we use is essentially a four-step procedure: a diagnostic scan, placement of the needles and sheaths, a temporary test block, and a neurolytic alcohol ablation.

Diagnostic Scan

During a routine diagnostic scan, I look for any signs of an active process that should not be blocked. Under this category I have diagnosed and deferred patients with

emphysematous pancreatitis, small bowel obstruction, or disease so extensive that a block would not be of any benefit. In the last category I exclude patients who have disease so extensive that the tumor is invading the musculoskeletal portions of the retroperitoneum. The pain will be carried by somatic sensory fibers; a celiac block will not significantly ablate the pain in such patients.

Before insertion of the needles, I ask the patient to grade their pain on a scale of 0 to 10, 0 being normal and 10 being unbearable. This scale is used for a reference value after the test block to help decide if the alcohol should be injected. To facilitate this, I ask that the patient not have pain medication the morning of the procedure so the pain level can be used as a guide during the procedure.

Placement of Needles

We position the patient in the left decubitus position (i.e., right side up and the left side down) if a unilateral block is to be used, or prone if a bilateral is used. One can thus easily approach the left side from almost a straight

Figure 61-139. Scan of a patient in the right decubitus position after injection of air into the retroperitoneum. The air (arrow) crosses from left to right in the plexus area.

angle and the right side with a more oblique approach (Figs. 61-138 to 61-140, if a bilateral block is required).

The trajectory chosen is slightly angled, with the entrance point at the level of the renal vein and the target area just above the superior mesenteric artery, which is easily seen. The needle is angled slightly so that the final placement will be adjacent to the side of the aorta at a level between the celiac and the mesenteric artery.

If an appropriate placement of a single needle is made, the block can be accomplished with a single needle placement (Fig. 61-139). Injection of gas shows the gas crossing the midline, which indicates the injected alcohol will cross from left to right and ablate the major portion of the plexus. If the gas does not cross sufficiently from the left side, a placement of a second needle from the right side should be performed (Fig. 61-140).

Test Dose

Once successful placement of a left side needle has been made, a test injection is performed. I inject 15 mL of 2% lidocaine on the left side and 3 to 4 cc of ambient room air. I then repeat the CT scan over the area of the needles to assess the distribution of the air in the abdomen. If the air crosses from left to right, covering the entire area, a unilateral block is performed. If the air does not cross, a bilateral block is performed.

I let the medication permeate for 10 minutes and then ask the patient to grade the pain. If there is a remarkable improvement in their grading scale (i.e., a reduction from 8 or 9 to 0 or 3) and if the air has not tracked into an inappropriate area, the final block is performed. In some cases when the patient has a tumor and the patient requests it, I will inject the alcohol despite a poor response because this may be the last resort. If a bilateral block is required,

we typically finish the left-sided procedure completely and then insert the needle on the right side.

Neurolytic Alcohol Ablation

The alcohol for the final block is not injected if there is no relief of pain or if there is an inappropriate tracking of the air. The tracking of the air is a good indicator of where the alcohol will go. A radiologist who did not follow this guideline produced a severe case of posterior mediastinitis because the alcohol tracked into the chest; the test study showed air tracking into the mediastinum, but he disregarded it. If the air tracks posteriorly adjacent into the nerve area behind the psoas muscle or the mediastinum area, I do not inject the alcohol on that side because of possible nerve damage. The "marker" of gas is a worthwhile portion of the examination. Fluoroscopy and ultrasound cannot evaluate this effectively, and catastrophes may result.

Also, if there is a return of blood from the needles, do not inject the alcohol. If a vessel is injected with alcohol, destruction of the end organ (e.g., kidney, spinal cord) will result.

At this time the alcohol is injected very slowly into the unilateral or bilateral needles. Because of the effective outcome of our procedures, we have reduced the volume of alcohol injected (since our prior edition) from 25 mL to 15 mL of alcohol. If a unilateral block is performed, a single dose of 15 mL is injected. If a bilateral block is performed, 15 mL is injected on each side. (Plastic syringes must be used because with glass syringes the evaporation of alcohol is so rapid that the barrels will "lock up.")

Since the previous edition of this book, I have learned a valuable lesson from my anesthesia colleague Dr. Mark Boswell,³⁴ who has shown me that if one injects the alcohol very slowly, the discomfort is minimal to the patient. In the previous edition we reported rapid injection of alcohol, which produces intense pain that has been described as the sensation of being "kicked" in the abdomen.

In some cases the pain may involve the diaphragm, chest, or back because of referral pathways. The distribution can be anticipated by noting the distribution of the "air marker."

Follow-up

After the procedure, the patient is returned to his or her room on a stretcher and kept at bedrest for 8 hours. This time permits resolution of the potential orthostatic hypotension. This routine is important to follow; testing for orthostatic hypotension is inadvisable. One patient in our institution was made unconscious three times by three different resident physicians who wanted to test her orthostatic hypotension by taking her blood pressure in an upright position. She had a very bad headache after these "tests" but did fine after the appropriate bedrest.

Side Effects

Two side effects—temporary orthostatic hypotension and bowel irregularity—can occur. Interruption of the sym-

Figure 61-140. A, Scan with the patient in the right decubitus position shows a needle adjacent to the superior mesenteric artery. Note the small amount of tumor encasing the anterior portion of the vessel. B, Injection of air shows the gas localized by the artery. It does not cross the midline, indicating that coverage of the right side will not occur and the need for right-sided treatment. C, Placement of a right-sided needle is performed. The tip is between the crus of the diaphragm and the vena cava. D, Injection of air shows gas distributing only on the right side.

pathetic fibers stops the physiologic vascular tone in the splanchnic vessels, resulting in their dilation. The dilation produces pooling of blood; therefore if patients attempt to stand after a completed block, they will lose consciousness. If patients remain at bedrest for 8 to 10 hours, the problem resolves spontaneously. They should be gradually raised to the sitting and upright positions after the period of bedrest.

With interruption of the parasympathetic fibers, motility of the bowel changes so that some patients have diarrhea

and some inexplicably complain of constipation, which is manageable with over-the-counter stimulants if needed.

Complications

In the past 27 years I have had only two transient complications. One patient had hematuria for 2 days, and one developed a small subcapsular renal hematoma. Com-

Figure 61-141. CT scan of a patient shows the air “marker” tracking into the chest (arrows) behind the crura. Injection should not be made in such cases, or mediastinitis may develop.

plications from the blind or other guidance methods are many and severe, including death, paraplegia, loss of kidneys or liver, hemorrhage, and mediastinitis (Figs. 61-141 and 61-142).

Briefly, there have been two other distinctly different methods reported in the literature: a transaortic method and an anterior approach.

Lieberman and Waldman²⁴² reported a transaortic approach in which the authors planned a trajectory to traverse the aorta. Once penetration of both walls of the aorta was accomplished, the alcohol was injected. Two groups have reported on a direct anterior needle approach with penetration of anterior structures such as liver and pancreas. Once the needles are in place, the appropriate medications are injected.

I do not favor either of these approaches because of possible problems associated with tracking of the alcohol and potential complications. If additional reports confirm the beneficial results and safety of those reports, one might

Figure 61-142. Radiograph of a patient with fluoroscopic localization for a celiac nerve block shows injection of contrast material (arrow). Permanent paraplegia developed after the procedure, despite the interventionist's considerable fluoroscopic experience and meticulous fluoroscopic technique.

consider these as alternative methods to the preferred one reported earlier.

Unfortunately, there is a tendency not to report complications with such invasive procedures, so it is difficult to assess the complication rates with the different approaches. However, Fitzgibbons et al⁹² reported a case of superior mesenteric vein occlusion associated with injection of alcohol from an anterior approach.

There have been three large international series reported by Prasanna,³³² Marra et al,²⁶² and Gimenez et al.¹¹³ Prasanna reported on 200 cases with good results for reduction of pain using a posterior unilateral left-sided block. Marra et al²⁶² and Gimenez et al¹¹³ used an identical anterior approach using a 22-gauge needle with injection of alcohol and reported significant difference in the outcome. Marra et al²⁶² reported that 21% were pain free at 15 days and Gimenez et al¹¹³ reported 61% pain free at 6 months.

Factors Affecting Pain Relief and a New Approach

Looking at the available results indicates that the exact anatomic approach used, needle size, or guidance modality is not a critical factor if adequate alcohol is delivered appropriately to the area of the celiac plexus. To ensure there is proper delivery of the alcohol it is prudent to use some type of marking agent (contrast material or air) prior to the injection of the alcohol to make sure no subtle adjustment of the needle tip is required. If the distribution of the contrast marker is not satisfactory, the needle should be moved and the contrast marker injection repeated. When the contrast marker spreads throughout the plexus area to the right and left, it is appropriate to inject the alcohol. Individual results observed in the various studies probably depends on how meticulous the operator is with the needle placement and contrast injection. Mixing contrast material with the alcohol is not useful because it simply documents the placement of the alcohol after injection. It does not permit assessment of needle position so that it can be adjusted. Another step we know is helpful is to inject local anesthetic into the celiac area prior to the alcohol to see if pain relief is relieved. If complete relief results, one can be confident that the alcohol will diffuse in a similar fashion. Also relative to pain control during the alcohol injection, the local anesthetic will make the process of alcohol less uncomfortable. The alcohol should be injected very slowly to minimize intense pain.

Another factor that strongly affects the outcome of celiac nerve blocks is the degree of tumor invasion or involvement of the plexus area by fibrosis. Akhan et al⁶ have shown that when tumor has invaded the plexus, alcohol will not distribute and may not ablate the nerve tissues. To further improve the results of plexus blocks, we have introduced a new technique that we believe offers great promise for the future of pain relief and perhaps even treatment of pancreatic cancer.

Radiofrequency Ablation of Celiac Plexus

Even though this method is just being developed, I want to introduce this new approach because it seems promising. If one reviews the subsequent section on tumor ablation,

one can reaffirm that ablation of tumor or tissues has been dependent on uniform and effective distribution of the ablative liquid agent into the target area. When a liquid is injected into solid tissue, whether it be tumor or the retroperitoneum with tumor, the liquid follows pathways of least resistance. When tumor is blocking the pathway for the alcohol, it may spread to unanticipated areas and can potentially cause complications. The use of liquid ablative agents has generally been replaced by radiofrequency heat coagulation because of this problem. Recognizing the benefits of radiofrequency for solid tumor ablation outside the pancreas, I decided to try judicious use of radiofrequency in a pilot group of patients who were not suitable for alcohol ablation of the celiac plexus. Although this might initially raise some safety concerns in the area of the pancreas where there are many vessels, it is an indisputable fact that large blood vessels act as heat sinks and are resistant to injury. The flowing blood carries the heat away from the area acting as a "radiation." For these reasons, it seems that radiofrequency might be an ideal methodology for ablating the plexus.

In a group of eight patients with intractable pain not suitable for alcohol block, we used radiofrequency to ablate the plexus. These patients had tumors in the peripancreatic area that we believed would impair the diffusion of alcohol into the plexus area.

Using a posterior or lateral approach, we inserted the radiofrequency probe with a 2-cm heating segment into the plexus area. The active portion of the probe could be visualized on the CT scan so that it could be carefully positioned next to the plexus area. The area was heated at 90°C for 10 minutes (Fig. 61-143). Realizing that this was the first such procedures performed, we were pleased with favorable results in six patients; two patients did not have good pain relief. The cause for failure was due to incorrect positioning of the probe in one patient and inadequate heating in the second. We are now in the process of

Figure 61-143. CT scan of patient during radiofrequency treatment of celiac plexus. Because the tumor had invaded into the plexus, successful treatment with alcohol was unlikely.

performing a Phase I study to determine the safety of this method in a larger series of patients.

Because we had no complications from these procedures, we are also contemplating the possibility that radiofrequency may be used in the future to palliate or treat pancreatic cancers themselves.

Percutaneous Cholecystostomy

Percutaneous cholecystostomy is accepted as a viable alternative to surgical cholecystostomy in cases of cholecystitis-producing sepsis. Although it is true that any guidance method may be used for performing the puncture of the gallbladder, all authors agree that puncture of the gallbladder through the hepatic "bare" side is important to prevent leakage and proper tract formation.

As one might imagine, CT is superior for such guidance and should be used when a high confidence level is desired. Selection of tubes is dependent on the operator's own bias, but in our hospital we have relied on a small-caliber pigtail to effect emergency drainage. If stone removal or other manipulation is intended, sequential dilation can be performed as needed (Fig. 61-144).

Many reports have appeared in the literature about percutaneous cholecystostomy that have highlighted the benefits and the difficulties.

Among the authors reporting (Van Sonnenberg et al,³⁸⁵ Hatjidakis et al,¹⁶⁷ Granlund et al,¹²² and England et al⁸⁰) there is consistent agreement that these procedures are effective and provide effective palliation for acute cholecystitis. Complications are quite varied and include bile peritonitis, bleeding, vagal reactions, hypotension, and acute respiratory distress. Rates vary between 4% and 10%.

All authors agree that the procedure, when optimally performed, uses a transhepatic pathway rather than a transperitoneal approach. Because of this uniform principle, I believe such procedures should be performed under CT guidance. In the past 15 years, we have never had a complication when the cases were performed and catheter positioned under CT guidance, compared to the 4% to 10% reported above.

Tumor Ablation

Radiologic ablation of tumors began in recent years with the acceptance of the surgical principles and outcomes that showed that removal of primary and metastatic lesions from the liver resulted in improved morbidity and survival rates of patients. The literature is replete with information by a number of authors who have devoted considerable effort and time to develop, introduce clinically, and refine these methods. The most notable of these are Gazelle,¹⁰¹ Goldberg,¹¹⁷ Solbiati,³⁶³⁻³⁶⁵ Lewin,²⁴⁰ Livrahi,²⁴⁷ Curley,⁶³ and others. The publications have been so numerous and rapid that it is difficult to properly reference all of those who have made contributions.

The enthusiasm for local treatment originated from the seminal work of several surgeons who performed meticulous resection of multiple nodules throughout the liver. These authors, most notably Minton, showed increased survival of these patients. Although this approach was considered remarkably controversial at the time, it represents the base under the current philosophy. Another cate-

Figure 61-144. A, Scan shows a needle puncture of the gallbladder through a cuff of liver (arrow). The needle was intentionally directed toward the gallstones (arrow). This was done in case there was a need for percutaneous removal of the stones later. B, Radiograph shows the needle in place adjacent to the gallstones (curved arrow). Theoretically, one could consider performing this study under fluoroscopy, but the margin of the liver could not be visualized in this manner. C, Radiograph shows insertion of the catheter in the gallbladder with contrast injection.

gory of patients who became recognized as amenable to the local destruction were those patients with hepatocellular carcinoma. Surgery is curative for those patients suitable for resection, but a significant number are not surgical candidates because of the size of lesions, proximity to vital structures, compromised status of the liver (cannot endure loss of functioning liver parenchyma associated with lobar liver resection), or generally poor health (Curley et al⁶³).

Surgical literature has definitely shown an increase in the survival rate of patients with metastatic colorectal and breast cancer. Taylor et al,³⁷⁸ Hugh et al, and Yoon and Tanabe⁴¹⁴ have shown survival rates at 5 years of 25% to 40%. With breast cancer, improved survival of 18% to 20% at 5 years was reported by Elias et al and Raab et al.

As a result of the general acceptance of the surgical principles, the methodologies appropriately evolved to simpler means of surgical treatment (cryoablation and heat ablation at open laparotomy) and ultimately to percutaneous application of the same methods. The trend is to further refine the percutaneous approaches knowing that the low morbidity and cost of percutaneous procedures will drive these simpler approaches. Even the surgical literature (Bowles et al,³⁶ Curley et al⁶³) confirms that the radiofrequency cumulative survival outcomes parallel the surgical results.

There are three major methodologies that have developed and are being refined by many centers. These consist of (1) application of various energy forms—freezing or cryoablation, heat application (including laser, microwave or radiofrequency); (2) injection of destructive liquid agents (alcohol, acetic acid, hot saline); (3) delivery of

chemotherapeutic agents directly into the tumor (angiographic injection is different); and (4) delivery of other sophisticated products such as DNA vectors, polypeptides, and hormones.

Cryoablation has been available for many years, but the instruments were so large that the methodologies were confined to surgical methods at open laparotomy. This method depends on repetitive freezing that produced death of tumor cells by creating ice crystals within the cells. Two freezing cycles were required to ensure reliable death of tumor cells. The advantage of this approach is that large tumors could be treated. The disadvantages were that there is a likelihood that large cracks in the liver can occur and result in a surgical repair. Another adverse outcome was that there was a systemic reduction in platelets, which would be problematic. Recently, smaller percutaneous probes have become available, but the issues related to liver cracking persist, and some results indicate that cell death by freezing is not as reliable as heat coagulation.

The development of heat application and injection of chemical agents evolved at about the same period, with the chemical agents becoming accepted quickly because of their simplicity and heat coagulation becoming more popular as the relevant technology evolved.

Alcohol and Other Chemical Agents

Percutaneous chemical ablation, typically with alcohol, is the most common minimally invasive method for treating hepatocellular carcinoma and metastatic lesions. It is low tech, economical, and available to any center in the world.

In recent years, it has been shown to be less effective than radiofrequency ablation for general metastatic disease and hepatocellular carcinoma (HCC) but it still remains an effective method for the treatment of HCC.

The effects of alcohol are caused by cytoplasmic dehydration, which causes coagulation necrosis, endothelial damage, platelet aggregation, local tissue ischemia, and ultimately fibrous reaction. Its advantages are that it is only locally destructive, can be metabolized readily, and does not typically cross major anatomic boundaries. It is effective for HCC because it typically has well-defined borders that confine and restrict the spread and localize the effects. Metastatic lesions are less well suited because the margins are less well defined and ethanol spreads in a more unpredictable fashion.

There have been two reported methods, best described by Shiina et al³⁵⁴ and Livraghi et al.^{246,248} The methods are similar in their approach for the injection of the material but differ in the quantity and intervals of injection. Both methods use a small-caliber needle, which is inserted into the most distal portion of the lesion and then is reinserted during injection of the alcohol to the lateral, posterior, caudad, cranial, and anterior walls of the mass. Shiina et al³⁵⁴ calculated the amount of alcohol to be used by using a volumetric calculation of a sphere:

$$\text{Volume} = 4/3 \pi (R + 0.5)^3$$

The volume is in cubic centimeters and R is the radius of the lesion. An additional 0.5 cm is added to account for spread into the margin of the lesion with the normal liver with anticipation that this may produce a chemical margin of the lesion. The injection is made over 10 to 20 minutes with some modification based on the patient's compliance. Typically a second treatment was performed several months later.

Livraghi et al²⁴⁸ used ultrasound to monitor the injection of alcohol with no precalculated volume specified. Their procedures were performed under general anesthesia to permit better pain control and management of ventilation. With their method the lesion was monitored with ultrasound and the injection was continued as long as the "flow" from the end of the needle continued without undue injection pressure. With their method they carefully infiltrated all walls as well as the central portion of the lesion. Repetitive injections were performed over several months if repeat imaging studies showed evidence of non-response or recurrence.

Follow-up was consistent in several perspectives. There was invariably a transient rise in the liver enzyme profiles, which returned to normal within 10 days. Blood alcohol levels were elevated postprocedure, and Shiina et al³⁵⁴ noted mild intoxication in 25% of patients. Successful treatment of confined or encapsulated tumors showed significant reduction in the alpha-fetoprotein levels.

Complications were not infrequent (Livraghi et al²⁴⁸ and Shiina et al³⁵⁴). The most common adverse effect was localized pain during and following the procedure. Pain persisted for several days with upper abdominal discomfort, enhanced by palpation, but this was easily controlled by analgesics. Patients may have spread of alcohol to uninvolved areas of the liver and produce necrosis of normal

tissue. Both authors reported intraperitoneal bleeding when a normal "cuff" of normal liver did not exist below the capsule.

Barnett and Curley¹⁸ and Livraghi et al²⁴⁷ summarized the general results of alcohol ablation as follows. For HCC, the success depends on the size of the lesions. With lesions less than 5 cm, ethanol injection was successful in 75% of lesions that underwent subsequent resection. With lesions between 5 and 8 cm, the ablation rate is 60%. Livraghi et al²⁴⁷ reported a 1-year survival rate of 90% and a 3-year survival rate of 63% (Figs. 61–145 and 61–146).

A comparison study of alcohol injection and radiofrequency ablation was performed by Livraghi et al²⁴⁷ and Ikeda et al.¹⁸⁶ Livraghi et al reported better results with HCC tumors less than 3 cm for radiofrequency than alcohol injection; however, there were higher complication rates with radiofrequency. Ikeda et al¹⁸⁶ studied small HCC lesions and found almost identical results of success and complications but favored radiofrequency because it required fewer treatment episodes.

Ethanol injection has much less effect for metastatic lesions and therefore is seldom used, in favor of radiofrequency treatment (Solbiati et al^{363, 364, 365}). The recommendation by most authors is to use alcohol injection when lesions are in an opportune site for radiofrequency or when lesions are greater than 3 to 4 cm.

As a final comment, other agents have been injected such as acetic acid (Ohnishi et al) and gel cisplatin (Engelmann et al⁷⁹), but the techniques still show the disadvantages of irregular distribution and therefore nonuniform response.

Heat Coagulation by Radiofrequency

Application of heat effectively kills tumor cells in two methods depending on the temperature. At 42°C tumor cells may die in preference to normal cells because of the induction of hypermetabolism from increased temperature. Because tumor cells lack the normal homeostatic controls of normal cells, they typically die a metabolic death over many minutes. With temperatures at 45° to 60°C intracellular proteins denature and bilipid membranes melt, resulting in cell death. With temperatures above this level (80° to

Figure 61–145. CT scan shows injection of alcohol into a large mass in the epigastrium. Note the distribution of alcohol is irregular (arrows). Because the distribution is so irregular, effective treatment of large tumors is difficult.

Figure 61-146. A, Baseline scan shows the placement of a needle into a low-density metastatic tumor from leiomyosarcoma. B, Scan shows 22-gauge needle in place within the tumor. Note the low-density gas within the lesion. The distribution of the gas follows exactly the distribution of the alcohol (see text). C, Follow-up scan several weeks later shows improvement in the appearance of the mass. Also note the needle and gas in a more anterior lesion in the liver, which is being treated during this later study.

110°C) heat coagulation necrosis occurs for all tissues. The temperature levels and effects reported by different authors vary slightly, but this is probably due to minor differences in the basic models studied and differences in cell types.

One critical factor that must be mentioned is the influence of blood flow both microscopically and macroscopically on the effect on local tissues and the survivability of normal and tumorous cells. Flowing blood acts as a heat sink or radiator effect so that heat is moved away from the immediate site of the treatment region. This result is helpful because one wishes to preserve normal vessels in close proximity to the tumor, but it has a negative effect on the survival of tumor cells in immediate proximity to the vessels. The residual tumor cells within tumors or especially at the margins of the treated areas are the cause of local recurrences (Curley et al,⁶³ and Sobiati et al³⁶³⁻³⁶⁵).

Relative to the methods of heat application, radiofrequency heat coagulation remains the preeminent method for heat coagulation. Laser, microwave, and ultrasound heating have been attempted and are being refined, but there is little indication they will provide heat deposition superior to that of radiofrequency.

Radiofrequency Devices

There are two major types of radiofrequency devices used for these treatments. One is a single probe and the other type is a spoke device, shaped somewhat like an

umbrella. The single-probe device is our preferred one because placement of the device is more easily achieved and has a better definition of the probe into the tissues, because it has a simpler configuration. I cannot comment on the efficiency of the other type of device because I do not have the experience.

General Technique and Placement of the Radiofrequency Probe

Preprocedural Steps

Patient selection criteria have varied among the various authors. Considering the motivation of cancer patients, there is little question that one could select almost any patient, but the most rational and human approach is to select only those patients who are likely to derive a direct benefit in survival or symptoms. The presence of multifocal disease in widely spread sites is a relative contraindication. In most cases patients being considered will be those with liver metastasis. It has been well established that the successful treatment of tumors is closely related to size because of the difficulty in treating patients with larger lesions. Solbiati et al,^{363, 364} Lewin et al,²⁴⁰ and Livraghi et al²⁴⁷ have shown that lesions smaller than 3 cm are likely to have a good outcome. Livraghi et al in a multi-institutional study involving metastases showed that lesions less than 2 cm were cured, lesions between 2 and 3 cm had a cure rate of 70% (recurrence rate of 30%), and lesions

greater than 3 cm had a cure rate of 58% (recurrence rate of 42%). The success and recurrence rate with HCC is similar. HCC lesions less than 2.5 cm are effectively destroyed while large lesions are prone to recur (Curley et al,⁶³ Bowles et al³⁶).

Assessment of lesions prior to the procedure relative to vascularity is important. Patients with lesions that are highly vascular as demonstrated by CT or MRI flow studies are less than optimal candidates. Patients with metastatic lesions from colon and breast are considered good candidates.

Exclusion criteria include the presence of severe coagulopathy, renal failure, jaundice, or anatomic issues related to proximity. It has been shown that if lesions are too close to the gallbladder, hilum, or bowel wall, injury may occur. A distance of 1 cm from these structures is considered adequate to prevent severe damage. Likewise, close proximity to major vessels is considered a relative contraindication because such vessels reduce the efficiency of heating and thereby reduce the local coagulation benefit.

Procedure Steps

Before the insertion of the probe, several important items must be addressed. If the lesions are in the liver, one should decide whether to give a dose of antibiotics. Solbiati³⁶³⁻³⁶⁵ recommends 2 g of ceftriaxone; in view of the occasional issues raised with infection, this seems a rational approach.

The grounding pads must be attached to the skin to enable good conduction of the current from the electrode to ground. The skin should be shaved to permit good contact. The pads should be attached with the long side of the pads perpendicular to the long axis. Lack of good ground can result in local burns.

Anesthesia for these procedures can be deep sedation or general anesthesia. When one begins performing such procedures, it is appropriate to visit a center where such procedures are performed. Also during the initial cases, general anesthesia is helpful to ensure patient comfort. After the procedural steps are mastered, procedures can be performed under local anesthesia and intravenous medications consisting of fentanyl and midazolam. In all cases

one should plan the procedure to ensure optimal heating and treatment of all segments of the lesion. In each case this means planning single or multiple insertions to cover the area of the lesion.

Depending on which probe is used, one plans appropriately. Available devices have automatic feedback mechanisms that modulate the current appropriately. With the device made by radionics, the heating period should be 12 minutes, but final heating depends on the final temperature after treatment. If the final temperature after turning off the probe does not measure at least 60°C, additional heating is appropriate. In each case one should follow the recommendations of the equipment manufacturer. Multiple insertions require repetitive heating periods for each geographic site. The size and degree of the thermal lesion are dependent on the temperature achieved and the duration of the heat application.

The therapeutic response can be assessed in several ways: from imaging and from monitoring of changes in the tissue impedance measurements. Any of three imaging devices can be used to monitor visually the change in tissue appearance that indirectly reflects tissue coagulation. Ultrasound shows a change of increased echogenicity when tissue coagulates. MRI shows change in tissue signal during coagulation of protein, changing the T2 appearance (Figs. 61-147 and 61-148). CT only shows imaging changes with injection of contrast material. It is not clear that any of these modalities offer great advantage one over the other so the choice of the modality is left to the reader, depending on their own experience and knowledge base (Figs. 61-149 to 61-151). The intent of monitoring the lesions under imaging is to produce necrosis of a "cuff" of tumor free area by necrosing 10 mm of adjacent normal liver.

When tumor has undergone heat coagulation, the impedance (or conductivity) increases; if the change has increased by 20 Ohms there is usually complete necrosis. Goldberg et al¹¹⁷ compared the amount of tissue necrosis produced by constant current flow over a finite period and variable current flow adjusted according to impedance changes. If the impedance rises too quickly (or electrical conductivity decreases) due to local tissue charring, con-

Figure 61-147. CT scan shows a large mass in the porta region of the liver (arrows). This was treated under MRI by radiofrequency treatment. B, Follow-up scan shows a low-density mass (arrow) representing the necrotic treated area. The large enhancing rim (curved arrows) represents recurrent tumor.

Figure 61-148. Turbo spin-echo T2-weighted oblique axial (A) and coronal (B) images obtained during MRI-guided radiofrequency (RF) thermal ablation. During the ablation session, T2-weighted and STIR images allow assessment of the developing zone of tissue damage, seen as a hypointense region surrounded by a bright ring of edema at the tip of the RF electrode. These images are intermittently acquired during the ablation session to ensure ablation of the entire tumor and thin rim of surrounding normal tissue.

duction of heat is not efficient. They found that if the current was reduced for 15 seconds after rapid rise of impedance, a greater volume of tissue was treated. This algorithm is the basis for the automated treatment mode of the single-probe device.

Follow-up after Therapy

For follow-up, CT or MRI is suitable for assessment of treatment but not ultrasound. Solbiati et al³⁶³⁻³⁶⁵ demonstrated that acute appearance of ultrasound changes cannot predict ultimate tumor necrosis. MRI shows hypointense

Figure 61-149. A, Turbo spin-echo T2-weighted axial image demonstrates a 1-cm metastasis near the dome of the liver. B, Turbo spin-echo T2-weighted coronal image demonstrates the radiofrequency electrode, placed under MRI guidance, with its tip centered within the tumor nodule. Axial (C) and coronal (D) contrast-enhanced T1-weighted images at the end of the ablation session demonstrate a hypointense zone corresponding to the treated metastasis. The lesion was treated to ensure complete ablation of the tumor plus a thin surrounding margin of normal tissue.

Figure 61-150. Scan through the chest shows a mass in the posterior mediastinum, containing calcium. The probe is located in the mass for ablation. Especially in the lung, it is critical to localize the treatment portion of the probe completely in the mass so that no contiguous tissues are damaged.

areas of unenhanced T1 and T2 images, which do not enhance with gadolinium injection. With CT scanning, necrosis of tissue can be appreciated only with the intravenous injection of contrast material. Size change can also be used. Those lesions that reduce in size or remain stable are considered necrotic. Those that increase are classified as progressing. Any appearance of recurrence indicates a need for retreatment if clinically relevant.

The major shortcoming with any of the radiofrequency methods (also shared by cryoablation) is the survival of viable residual tumor cells within the lesions or at the periphery of the lesions (see Fig. 61-147). Virtually all authors note that the most common site of recurrence is at the margin of the lesions. Despite the fact that the intent is

Figure 61-151. CT-guided ablation of a retroperitoneal lymph node. An approach through the anterior abdominal wall was used because this was the shortest unimpeded pathway.

to create a margin of tumor-free tissue, this is problematic. None of the imaging devices can accurately display small tumor rests at the margin of the lesions, so improvement will come only when further advances are made, probably with some method of multimodality treatment.

Multimodality Approaches

Combination with multiple other materials or agents have been evaluated in a preliminary fashion to enhance or increase the effects of radiofrequency. Several authors (Curley⁶³ and Hamilton¹⁶³ and Goldberg et al,¹¹⁷) have injected saline in different volumes and concentration and found that the resulting coagulation area was increased.

Goldberg et al,¹¹⁷ studied the benefits of combining radiofrequency ablation with ethanol injection and doxorubicin injection into the tumor site with animal models. With ethanol injection, they found increased area of coagulation when the ethanol was injected prior to the radiofrequency heating but no improvement when ethanol was injected following the radiofrequency ablation. The size of the lesion increased from 6.7 mm from ablation alone to 10.1 mm with the ethanol combination. Increase in the tissue impedance was found after the alcohol injection. This group also injected the chemotherapeutic agent doxorubicin into the tumor before and after radiofrequency ablation. The authors found that doxorubicin improved tumor coagulation when it followed the ablation but not before. The increase in the ablation site changed from 6.7 mm in the ablation site alone to 11.1 mm with the combination therapy.

Percutaneous Enteric Stoma

A logical extension of the percutaneous puncture and catheter insertions is the development of percutaneous methods for insertion of catheters into bowel loops.

Percutaneous gastrostomies and other enterostomas may be performed by fluoroscopy; they are not discussed in this chapter. Catheter insertion into the colon, however, is quite different and may require the use of CT for optimal placement of the entrance site.¹⁴² CT is well suited to ensure that the entrance site is on the retroperitoneal side of the colon so that peritoneal spillage will not occur. One author has used this for treatment of Ogilvie's syndrome.⁶¹ I have used it for catheter-instilled antibiotics in a case of toxic megacolon.¹⁴²

Multislice Helical Computed Tomography: Clinical Applications

Kenyon K. Kopecky, Jonas Rydberg,
Thorsten R. Fleiter, Kenneth A. Buckwalter

Applied Principles

Multislice helical computed tomography (MSH CT) is superior to *single-slice* helical CT (SSH CT) for all clinical applications. The principal technical advance brought forth with this new generation of CT scanners is increased speed. The new "quad slice" scanners simultaneously acquire four "slices," or "channels," of contiguous spatial information. In addition, the gantry rotates at up to two revolutions per second (0.5 second per 360-degree rotation). Because most SSH CT scanners acquire one slice of data per rotation at a rotation speed of one revolution per second, the new MSH CT scanners are up to eight times faster. The increased speed provides many benefits, including:

1. *Improved patient tolerance.* Because the examination can be performed very quickly, the patients are in the CT suite for only a few minutes, which may help save the lives of unstable, critically ill patients. Patients who are in pain and those who experience severe claustrophobia also benefit.
2. *Improved temporal resolution.* Faster scanning decreases motion artifacts in the CT images, which result from voluntary and involuntary movements. Voluntary movement arising from skeletal muscle activity may occur when patients are unable or unwilling to lie still or suspend respirations during the examination. Involuntary movement results from cardiac pulsations, respiratory motion, intestinal peristalsis, and so on. All motion artifacts are reduced with faster data acquisition. In addition, new techniques are being used to synchronize scanning with the heart to minimize artifacts from cardiac motion.
3. *Improved spatial resolution.* Some of the improved temporal resolution can be traded for improved spatial resolution by selecting a thinner slice width for data acquisition. With thinner slices, the spatial resolution along the longitudinal (z) axis of the patient is improved. This reduces partial volume artifacts and increases diagnostic accuracy.
4. *Improved contrast medium use.* Iodinated contrast medium is administered intravenously (IV) at higher rates, resulting in higher peak enhancement values, which

occur sooner after the start of injection. This improved *contrast resolution* increases the conspicuity of both normal and diseased tissues. Because scanning is completed rapidly, a shorter period of enhancement is needed; thus, for certain examinations, the dose of contrast medium may be reduced.

5. *Improved image quality.* The x-ray tube current (milliamperes [mA]) may be increased without risk of overheating because the scan is completed rapidly. Increasing the current decreases image noise and improves image quality, which is especially important when scanning very large patients and when using very thin slices.
6. *Increasing patient throughput.* Because scanning is completed more rapidly, more patients can be scanned per hour. This decreases the cost of the examination, which is especially important as reimbursements for medical care decline.
7. *Improved use of the x-ray tube.* Because imaging is completed more quickly, heating of the x-ray tube is diminished, which decreases or eliminates the need to wait for tube cooling between scans. In addition, many more images are created during the lifetime of a tube installed in a multislice scanner compared with that in a single-slice scanner, decreasing glassware costs and downtime.

Not all of the benefits of faster scanning described here can be realized simultaneously in each patient. The operator must choose faster speed, thinner slices, or lower noise or some compromise, permitting modest improvements in some of these factors.

In addition to these improvements, there is another innovation with multislice technology: the ability to use slice widths of less than 1 mm. Because of the large penumbra encountered when the x-ray beam is collimated to less than 1 mm, the radiation dose to the patient is unacceptably high with submillimeter SSH CT. With MSH CT, slices thinner than 1 mm can be created while the overall beam collimation remains at 1 mm or larger. This allows for high-resolution, *isotropic* imaging (i.e., imaging with equal spatial resolution in all three orthogonal planes, resulting in a cube-shaped voxel). The main advantage of isotropic

imaging is that reformation of the image data into any inclined plane results in the same resolution and image quality as the originally acquired slices. When a small x-ray focal spot is used, the pixel size in the scanned plane is approximately 0.5×0.5 mm. To achieve isotropic, high-resolution imaging, the slice width must be 0.5 mm, which is possible only with multislice CT.

MSH CT creates larger data sets, which present new challenges for the radiologists, technologists, network administrators, and medical equipment vendors. A chest CT examination performed with a slice width of 2.5 mm may generate more than 200 slices. A multiphase examination of the abdomen and pelvis or a CT arteriogram may generate more than 1000 slices. These huge volumes of image data result in increased image reconstruction time, increased transfer time, increased archival costs (the Picture Archival and Communication System [PACS] or film), and challenges for image review and interpretation. MSH CT scanners also cost more than SSH CT scanners and require more powerful workstations. Image interpretation requires the increased use of auxiliary display techniques such as (1) workstation review of source images in leaf (scrolling) mode, (2) multiplanar reformatting, (3) maximum and minimum intensity projections, (4) volume rendering, (5) virtual endoscopy, and (6) three-dimensional (3D) shaded-surface display.

Because of the advantages described here, MSH CT is superior to SSH CT for nearly all clinical applications. In addition, new applications of CT scanning are arising that had been previously impossible with SSH CT. As a result of its spectacular diagnostic power, MSH CT replaces more costly or more invasive medical diagnostic procedures, leading to earlier and more accurate diagnoses with reduced costs. This chapter highlights some of the indications for which MSH CT promises to have a major impact in patient care and clinical outcomes and is divided into sections based on organ systems: neurologic, cardiovascular, thoracic, abdominal, and skeletal. Because many organ systems may be examined in a matter of seconds with MSH CT, a discussion of multiorgan systems is added.

The information presented in this chapter cannot replace that covered in depth in other chapters of this text. Clinical materials were chosen that illustrate applications of CT that either are greatly improved by the multislice technique or were impossible before the introduction of the technology. The applications illustrated here represent only a few exam-

ples of the usefulness of MSH CT and not a comprehensive catalog of clinical indications. All CT scans reported in this chapter were performed on the MX 8000 scanner (Marconi Medical Systems, Inc., Cleveland, Ohio), and all postprocessing work was performed on the MX View workstation (Marconi Medical Systems). For this chapter, we used the definition of pitch suggested by McCollough and Zink,⁴ which applies equally well to SSH CT and MSH CT:

$$\text{pitch} = \frac{\text{table travel per gantry rotation}}{\text{total nominal scan width}}$$

Clinical Applications

Neurologic Imaging

High-resolution, thin-section direct axial and coronal nonhelical CT used to be the standard technique for temporal bone imaging. A study¹ comparing the previous standard technique with MSH CT using isotropic voxels (0.5 mm) found MSH CT to be superior for visualization of the anatomy. Coronal views were created from the source images using multiplanar reformatting software. In addition, the MSH CT examination is much faster and more comfortable for the patient because it eliminates the hanging head position for direct coronal scanning. The radiation dose is lower in MSH CT because direct coronal scanning is eliminated (Fig. 62-1).

Surgical planning for the treatment of aneurysms of the circle of Willis requires superb visualization of the aneurysm and its relationship with arterial branch vessels and surrounding structures. Conventional angiography offers excellent spatial resolution, but the procedure is invasive and expensive and in rare cases may cause significant neurologic complications. In addition, only a limited number of views are possible because each projection requires a separate injection of contrast medium and a series of radiographic exposures. MSH CT angiography with isotropic 0.5-mm voxels offers high-resolution, minimal invasiveness without the risk of neurologic complications, a much lower cost, and an infinite choice of viewing projections (Fig. 62-2).

At our institutions, the neurosurgeons come to the workstation before surgery to rotate the 3D images with the track ball to ensure that they understand the anatomy from

Figure 62-1. Bilateral chronic otitis media and cholesteatoma. Isotropic multislice helical CT was performed with 0.5-mm slice width. A, Axial image shows opacification of both middle ear cavities, mastoid antrum, and mastoid air cells as a result of chronic otitis. B, Coronal reformat provides excellent spatial resolution and depicts the cholesteatoma with erosion of the ossicles (*straight arrow*) and scutum (*curved arrow*).

Figure 62-2. Middle cerebral artery aneurysm in a 60-year-old man who presented with headaches. Multislice helical CT was performed with a slice width of 0.5 mm and a reconstruction increment of 0.2 mm. Maximum-intensity projection axial (A) and oblique (B) images show a middle cerebral artery aneurysm (arrows).

all projections. In addition, because of its higher spatial resolution, MSH CT angiography is preferred to magnetic resonance angiography (MRA) in the preoperative evaluation of cerebral aneurysms, although both techniques are powerful and have different strengths and weaknesses.

Perfusion imaging is used clinically in magnetic resonance imaging (MRI) to evaluate stroke patients. The advent of MSH CT improves the capability of CT for the measurement of blood flow in tissue. Before scanning begins, the tabletop is locked in a predefined position to cover the region of interest (usually the middle cerebral artery and its distribution). Fifty milliliters of contrast medium is injected at a rate of 5 to 10 mL/sec into an antecubital vein, and scans are obtained every 2 seconds for about 30 seconds. The computer records the density in every pixel in every image, beginning before the contrast medium reaches the organ of interest and continuing until after the bolus has passed. The computer then measures the rate at which the brain tissue density increases with time. The maximum rate of increase is normalized to the arterial peak enhancement to obtain a blood perfusion value for each pixel.

In addition, the computer calculates time to peak enhancement and the mean transit time of the bolus through the brain. Color maps of the different functions are created and displayed (Fig. 62-3). The information gleaned from this test may help distinguish areas of reversible from irreversible ischemia.³ The disadvantages of this technique relative to MRI are (1) the limitation on the volume of

brain tissue that can be studied (width of detector array) and (2) the inability to perform diffusion imaging.

During the 1990s, MRI became the principal imaging modality for evaluating the spinal canal and surrounding structures. Some surgeons, however, preferred to use CT in conjunction with myelography because of CT's ability to depict the bony structures in fine detail. With MSH CT, a wide anatomic zone of the spine can be scanned with the thin-slice technique. For example, the cervical spine can be scanned with 1-mm slice thickness in 30 seconds or less, providing isotropic, 1-mm resolution in all planes (Fig. 62-4). Another indication may be radiculopathy, in which IV contrast-enhanced MSH CT may be used to distinguish soft from hard disc disease.

Cardiovascular Imaging

CT angiography is possible with single-slice helical technology, but it is severely limited by the acquisition of only one slice of data at a time. Thus, either the volume of anatomic coverage must be very limited, or the image quality must be compromised by the choice of thick slices (poor z-axis resolution) or high pitch (high noise, more artifacts). With the advent of MSH CT, CT angiography has become a powerful clinical diagnostic tool for the evaluation of a wide variety of vascular diseases, supplanting other imaging modalities, including conventional angiography.

Figure 62-3. Brain perfusion study in a 64-year-old woman who presented with acute left hemiplegia caused by acute right internal carotid occlusion. The unenhanced CT was normal. Perfusion study was performed with 4×5 -mm dynamic axial scans every 2 seconds through a single brain location. Density curves that are proportional to contrast concentration were generated from brain parenchyma, an arterial input vessel, and dural sinus. These curves were used to generate the cerebral blood flow (CBF) (A) and time-to-peak (TTP) (B) maps, demonstrating decreased cerebral blood flow (blue) and increased time to peak (red) within the right cerebral hemisphere.

Figure 62-4. CT myelogram of a 67-year-old man with a history of cervical and lumbar fusion. The patient had presented with neck and back pain. The cervical scan was performed with a 1-mm slice width, rotation time of 0.75 second, pitch of 1, and scan time of 44 seconds. Sagittal (A) and axial (B) images show fused vertebra with osteophytes that impinge on the spinal cord.

Concurrent with the development of less invasive diagnostic imaging techniques has been the development of less invasive surgical techniques. One example of the marriage of less invasive imaging with less invasive surgery is the use of MSH CT angiography with endoluminal repair of aortic aneurysms using stent-grafts. At many institutions, MSH CT has completely supplanted conventional angiography in preoperative and postoperative evaluations of patients with aortic aneurysms (Fig. 62–5). MSH CT not only

is less invasive and less expensive but also provides more information. Accurate measurements of the aneurysm and its relationship to branch vessels are made on the preoperative study, which are used to determine whether a patient is a candidate for endoluminal therapy. If the patient is a candidate, the proper diameters and lengths of the modular graft components are selected using the CT data. Postoperatively, MSH CT is used to assess patency of the endograft and to detect complications such as endoleaks.

Figure 62–5. Aortic stent-graft in a 69-year-old man who underwent endoluminal repair of an abdominal aortic aneurysm. Postoperative multislice helical CT demonstrated graft patency and absence of an endoleak. Anteroposterior maximum-intensity projection (A), 3D surface-shaded display (B), and virtual arterioscopy (C) images show the wire frame of the stent-graft within the aorta. C, View from the superior portion of the abdominal aorta looking caudally into the celiac trunk (asterisk) and the main aortic lumen (A).

Figure 62-6. Coronary calcium scoring. Multislice CT was performed in nonhelical mode using prospective electrocardiographic triggering, 0.5-second rotation time, 180-degree interpolation, and 0.3-second image acquisition time. The image acquired during diastole shows heavy calcifications (*arrows*) in the left anterior descending coronary artery and no visible motion artifact.

Imaging of the heart with helical CT had been limited by the rapid motion of the heart relative to the slow data acquisition times of CT. With the advent of multislice technology, some cardiac imaging applications have become more feasible. The simplest of these is *cardiac calcium scoring*, which refers to the quantitative measurement of calcium within atherosclerotic plaques in the walls of the coronary arteries (Fig. 62-6). The fastest multislice scanners acquire four slices within 0.3 second using a 0.5-second rotation time and a 180-degree reconstruction algorithm.

There are two ways to synchronize the CT data acquisition to the heart motion: (1) *prospective* electrocardiographic (ECG) triggering and (2) *retrospective* ECG gating.

Prospective triggering is used in a nonhelical mode, and it permits the x-ray beam to be turned on and off as the tube rotates around the patient. Some patients are not candidates for triggered imaging because of irregular cardiac rhythms. For calcium scoring, the x-rays are turned on during diastole, when the ventricles are relatively motionless.

Prospective triggering provides a lower radiation dose to the patient than retrospective gating because the x-ray beam is turned off during systole. With a slice width of 2.5 mm, the coronary arteries are imaged during suspended respirations in 15 seconds or less. The images have very little motion artifact, and future research will determine whether MSH CT is as accurate and reproducible as electron beam CT for calcium scoring.

MSH CT performed with retrospective ECG gating is being investigated for several uses:

1. Coronary CT angiography (Fig. 62-7).

Figure 62-7. Coronary CT arteriography. Multislice helical CT was performed during intravenous administration of contrast medium with 1-mm slice width and retrospective electrocardiographic gating. A, In the virtual arterioscopy image, the viewer is positioned within the left main coronary artery looking distally. In the direction of the *asterisk*, on the *dotted line*, the lumen of the anterior descending coronary artery is seen. *Upper left*, Proximal circumflex artery. For orientation purposes, the virtual endoscopy images are accompanied by a reformatted planar image (B) that displays the position of the viewer and the viewing direction (*open arrow*). The *asterisk* positions in A and B are identical. B, Visualization of left main artery (*curved arrow*), left anterior descending coronary artery (*straight arrow*), and circumflex artery (*arrowhead*). (Courtesy of Robert C. Gilkeson, M.D., University Hospitals of Cleveland.)

2. Assessment of ventricular ejection fraction.
3. Evaluation of ventricular wall motion.
4. Evaluation of ventricular perfusion.

To use helical CT with retrospective gating, the operator must choose a pitch of 0.5 or less to provide sufficient data throughout the cardiac cycle. If the operator chooses a nominal slice width of 1 mm, a rotation time of 0.5 second, and a pitch of 0.5, the time required to cover the entire heart is 30 to 40 seconds, which is longer than many patients can suspend respirations. Retrospective gating is less sensitive to cardiac rhythm irregularities than prospective triggering. The clinical acceptance of MSH CT for some of these applications may have to await further advances in CT, which promise to deliver rotation times of less than 0.5 second and more than four slices per rotation. There will be formidable competition from MRI for these same clinical applications.

Perfusion imaging with multislice CT, as mentioned, is being studied as a diagnostic tool in stroke patients. This technique can be used to evaluate blood flow in other organs, such as the kidney (Fig. 62–8). Perfusion CT may

prove complementary to CT angiography in the evaluation of arterial inflow obstructive disease. The anatomic information about renal artery stenosis, coupled with the functional information about renal perfusion, may prove more useful than either one alone.

Thoracic Imaging

Pulmonary embolism is a common cause of death, and until now, the methods of establishing the diagnosis have had significant drawbacks. The nuclear medicine ventilation-perfusion scan has low accuracy. Pulmonary arteriography, although accurate, is invasive, expensive, and not widely available. SSH CT has been used to evaluate patients with suspected acute pulmonary embolism, but the accuracy, relative to arteriography, is not sufficiently high. A prospective blinded multireader study revealed a sensitivity and specificity of 60% and 81%, respectively, for SSH CT, compared with arteriography.² MSH CT has the potential to replace ventilation-perfusion scanning and arteriography and to improve the diagnosis and outcome of

Figure 62–8. Aortic dissection. A CT perfusion study was performed through the midportions of the kidneys during intravenous administration of 30 mL of contrast medium at 10 mL/sec in a man with known aortic dissection. Axial images were obtained at 2-second intervals for 35 seconds. A, CT scan from the late arterial phase shows bright enhancement of the true lumen and lesser enhancement of the false lumen. B, Perfusion scan shows severe impairment of right renal blood flow (supplied via the false lumen) compared with the left. C, Graph of CT density versus time illustrates perfusion in the true lumen (A), false lumen (B), left kidney (C), and right kidney (D). CT arteriography followed the perfusion study (not shown). D, On a venous phase CT scan, enhancement of the kidneys appears equal, illustrating the limitations of conventional CT in the evaluation of perfusion.

Table 62-1. Multislice Helical Computed Tomography Technique for Acute Chest Pain and Dyspnea**IV Contrast Medium Administration**

Catheter size	≥20 gauge
Catheter location	Right antecubital vein
Medium type	Nonionic
Concentration	300 mg iodine/mL
Volume	1.5–2.0 mL/kg, up to 150 mL
Rate	4–5 mL/sec
Delay time	17–24 sec

Scanning Technique

Channels/rotation	4
Nominal slice width	2.5 mm
Pitch	1.0
Rotation time	0.5 sec
Focal spot	Large
kVp	120
mAs	230
Scan time	10–15 sec
Direction	Base to apex of lungs

Reconstruction Technique

Reconstruction field of view	To include lungs, excluding chest wall
Filter (algorithm)	Medium body
Reconstruction increment	1.0–1.3 mm
Matrix	512 × 512 pixels
Edge enhancement	0%

IV, intravenous; kVp, kilovolt peak; mAs, milliamperere-second.

patients with pulmonary embolism. Clinical trials are under way to determine the accuracy of MSH CT relative to arteriography.

MSH CT is powerful because it also can be used to diagnose many diseases that clinically mimic pulmonary emboli, such as pneumonia, pulmonary edema, aortic dissection, pericarditis, pleuritis, carcinoma that obstructs pulmonary arteries, bronchial obstruction, and esophageal rupture. The technique that we use to evaluate patients with acute chest pain or dyspnea is shown in Table 62-1. It is

possible to follow the chest CT with CT scans of the abdomen, pelvis, and legs to detect possible deep venous thrombosis, all with the use of just one injection of iodinated contrast medium (Fig. 62-9).

Abdominal Imaging

Multiphase examinations of the liver, pancreas, and kidneys are ideally suited to MSH CT because multiple scans with thin slices are needed in rapid succession, which is impossible with SSH CT. Multiphase examinations of the liver commonly are required for patients with hepatitis or cirrhosis to evaluate for hepatomas (hypervascular tumors are best seen during the arterial phase) (Fig. 62-10) and patency of the hepatic and mesenteric arteries and veins.

Multiphase examinations of the pancreas are usually performed to assess islet cell tumors, which are best seen in the pancreatic phase of contrast medium administration (Fig. 62-11). The onset and duration of the *arterial*, *pancreatic*, and *portal venous* phases depend on the rate and duration (volume) of contrast medium administration.

Tublin and colleagues⁶ compared the enhancement of the pancreas and the liver using two different contrast medium injection rates: 2.5 and 5.0 mL/sec. They found that the peak enhancement was higher and that the time to peak occurred sooner with the higher injection rate for both the pancreas and the liver (Fig. 62-12).

To take advantage of the increased enhancement associated with the higher injection rate, MSH CT must be used to complete the scans rapidly with thin slices. Ideally (in patients with normal cardiac output), the pancreatic phase images should begin at 40 seconds from the start of injection and last no more than 15 seconds; the portal venous phase images should begin at 65 seconds and last no more than 20 seconds.

Multiphase examinations of the kidney are performed for a number of indications, including the following:

1. Evaluation of renal masses to distinguish benign from malignant.

Figure 62-9. Pulmonary emboli and deep venous thrombosis. *A*, Multislice helical CT of the chest was completed in 15 seconds with 2.5-mm slice width. Emboli are seen within two segmental arteries: one oriented in the cephalocaudal direction (arrow) and the other in the transverse direction (arrowheads). *B*, The pelvis and legs were scanned beginning 2.5 minutes after the start of contrast medium injection; popliteal venous thrombosis (arrow) is seen.

Figure 62-10. Hepatoma. Dual-phase multislice helical CT was performed in a man with hepatitis C and cirrhosis. *A*, The arterial phase scan depicts an enhancing neoplasm (*curved arrow*) and its feeding artery (*straight arrows*). *B*, The hepatoma is also seen in the portal venous phase.

Figure 62-11. Insulinoma. A patient with symptomatic hypoglycemia was scanned in the pancreatic and portal venous phases. This pancreatic phase image shows an 8-mm hypervascular neoplasm in the tail (*arrow*).

Figure 62-12. Pancreatic and hepatic enhancement showing a comparison of two contrast medium injection rates. Compared with the slower rate (2.5 mL/sec), the faster injection rate (5.0 mL/sec) provided an earlier rise in parenchymal enhancement and higher peak enhancement. Multislice helical CT is ideally suited to take advantage of the superior enhancement afforded by the faster injection rate for dual-phase scanning of the pancreas and liver. (Adapted from Tublin ME, Tessler FN, Cheng SL, et al: Effect of injection rate of contrast medium on pancreatic and hepatic helical CT. *Radiology* 210:97-101, 1999.)

Figure 62-13. Renal donor evaluation. The multislice helical CT examination has three or more phases. In this potential donor, the arterial phase coronal (A) and axial (B) maximum-intensity projection images demonstrate two left renal arteries (arrows) and an early branching artery to the upper pole (arrowhead). C, The nephrographic phase disclosed a lumbar vein (arrow) merging with the left renal vein (arrowheads) as shown on an axial maximum-intensity projection image. D, On an oblique multiplanar reformat, a left gonadal vein (arrow) is shown merging with the left renal vein (arrowheads).

Figure 62-14. Virtual colonoscopy. Multislice helical CT was performed with 2.5-mm slice width after rectal insufflation of 2 L of carbon dioxide. A, This normal virtual endoscopy image was taken from the top of the hepatic flexure looking down into the proximal transverse colon. B, The overview image shows the viewer's position (open arrow) in A.

Figure 62-15. Calcaneal fracture of a 35-year-old man who sustained comminuted fractures of the right calcaneus and femur. Multislice helical CT was performed in the axial scan plane with 1-mm slice thickness. Sagittal (A) and coronal (B) reformats show fracture extent, number, and size of fracture fragments and violation of joint surface (*arrow*).

Figure 62-16. Wrist CT arthrography of a man who complained of wrist pain after playing golf. Multislice helical CT was performed (slice thickness of 0.5 mm, reconstruction increment of 0.2 mm) after contrast medium injection into the midcarpal and radioulnar joint spaces. The coronal reformatted image shows complete tear of the scapholunate ligament (*long arrow*), enabling communication between the normally separate midcarpal and radiocarpal joint spaces. The triangular fibrocartilage (*curved arrow*) is intact.

Figure 62-17. Os acetabuli of a 24-year-old man who complained of right hip pain. Multislice helical CT was performed with 1.0-mm slice thickness. An accessory ossicle (*arrow*) with sclerotic margins is shown on coronal reformat image (*A*), 3D surface shaded display image (*B*), and volume-rendered image (*C*). The volume rendering is performed with a high degree of transparency, emulating plain radiography.

2. Evaluation of urolithiasis and its complications.
3. Evaluation of potential renal donors.

Traditionally, the evaluation of potential renal donors included excretory urography (IV pyelography) and conventional arteriography. Now these two examinations have been replaced at some centers by MSH CT, and this single examination provides more information than the traditional examinations with less invasiveness and at a lower cost.

The less invasive MSH CT examination is perfectly suited

to complement the new less invasive surgery: laparoscopic donor nephrectomy. To perform a laparoscopic nephrectomy, the surgeon must have detailed anatomic information before surgery because he or she operates through a small umbilical incision with limited visibility and surgical exposure. All arteries, veins, and ureters must be identified before surgery to minimize the chance of surgical complications.

The MSH CT examination has three (or more) phases: (1) noncontrast, (2) arterial, and (3) nephrographic, plus an immediate post-CT plain radiograph.

The *noncontrast* (precontrast) phase is used to evaluate for urolithiasis and to provide baseline CT density measurements for any mass lesions that may be detected.

The *arterial* phase is used to identify all renal arteries, including accessory arteries, and to create three-dimensional images of the arterial anatomy.

The *nephrographic* phase is used to identify all renal veins, including anomalous veins, and communications between the renal veins, the gonadal veins, and the lumbar or azygos veins (Fig. 62–13). It is also used to identify any renal masses and to provide density measurements, which are compared with density measurements on the precontrast images. The plain radiograph of the abdomen and pelvis obtained after the CT scan is used to identify any abnormalities of the collecting system such as medullary sponge kidney disease and ureteral duplication.

Virtual colonoscopy (CT colography or colonography) is being investigated as a method of detecting colonic polyps. The examination is performed after a bowel-cleansing regimen. Air or carbon dioxide is administered per rectum, and the abdomen and pelvis are scanned without contrast materials. Some authors conclude that helical CT colonography, performed with a 5-mm slice width, is not adequate as a colorectal cancer screening test.⁵ With MSH CT, the entire colon and rectum can be examined using 2.5-mm slice width, pitch 1, in 25 seconds or less. Superior image quality is achieved with this technique (Fig. 62–14), and research is under way to compare it with conventional colonoscopy.

Skeletal Imaging

MSH CT is well suited for musculoskeletal imaging because (1) submillimeter slice thickness makes isotropic imaging possible and (2) the use of multiple detectors allows for greater coverage of regional anatomy with thinner slices, higher milliamperes, and lower noise.

High-resolution (small focal spot), isotropic imaging can be used for smaller regions of interest such as the hand, wrist, foot, and ankle. In scanning a traumatized extremity, the need for multiple scanning planes is eliminated. The limb is placed in a position that is comfortable for the patient. From the acquired volume of image data, any viewing plane can be reformatted (Fig. 62–15). MSH CT may be used in conjunction with arthrography to better visualize the joint spaces and articular surfaces (Fig. 62–16).

Skeletal MSH CT can be performed in the torso (shoulders, spine, pelvis, hips) using the large focal spot, creating 1-mm, isotropic voxels. Imaging of the hips may be performed with a slice width of 1 mm, a rotation time of 1 second or more, and a pitch of 1 or less, providing high-quality images with low noise levels (Fig. 62–17). These techniques are possible only with MSH CT because of the improved use of the x-ray tube output.

Multisystem Imaging

There are several clinical indications for imaging large portions of patients, including multiorgan systems, at one

setting, such as the neck, the chest, the abdomen, and the pelvis. These indications include multiple trauma, diagnosis and staging of cancer, and evaluation of sepsis (Fig. 62–18). These indications are sufficiently common and sufficiently important for all large medical centers to provide MSH CT capabilities.

Figure 62–18. Thymic rebound after chemotherapy in a 7-year-old boy with lymphoma who had completed chemotherapy 4 months earlier. CT was requested to assess for residual or recurrent disease. The neck, chest, abdomen, and pelvis were scanned (2.5-mm slice width) in 24 seconds with a single contrast medium injection. Coronal (A), sagittal (B), and axial (C) images show excellent intravascular and tissue enhancement and high spatial resolution. Multislice helical CT showed no evidence of lymphoma. The thymus (arrows) had grown in size over the previous 4 months, typical of rebound phenomenon after cessation of stress (i.e., chemotherapy).

Summary

The evolution of helical CT has made a great leap forward with the development of multislice technology. This advance is facilitating earlier and more accurate diagnoses, saving lives, and reducing the cost of health care. Future advancements will result in even faster, higher-resolution instruments, which will improve on present capabilities and add new clinical applications.

 epidermoid of, 536–537
 epidermoidoma of, 535
 lipoma of, 536–537
 mass(es) of, vs. acoustic schwannoma, 525, 528f
 meningioma of, 531
Cerebellopontine cistern, 94f
Cerebellum, 498f, 499f, 507f, 508f
 blood supply of, 265
 dysplastic gangliocytoma of, 153, 154f
 hemangioblastoma of, 174, 175f
Cerebral aneurysm, 285–291
 computed tomographic angiography of, 291
 computed tomography of, 287–289, 287f, 288f
 etiology of, 285–287
 fusiform, 286–287
 imaging of, 287–291
 incidence of, 285
 magnetic resonance angiography of, 289–291
 magnetic resonance imaging of, 289, 290f
 mirror, 286
 multiple, 286
 natural history of, 285
 pathology of, 285–287
 subarachnoid hemorrhage grade in, 287, 287t
 surgery for, follow-up after, 291
 types of, 285–286
Cerebral aqueduct, 107f
Cerebral artery, 90, 91f, 103f
 anterior, 95f, 98f, 99f
 infarction of, 263–264, 263f
 in herpes zoster vasculitis, 211, 212f
 middle, 94f–97f
 infarction of, 220, 222f, 258–263
 chronic, 261, 262f, 263
 imaging of, 260–261, 261f, 262f
 inferior division of, 258
 ischemia of, 247, 261, 261f
 subcortical territory of, 258
 superior division of, 258
 territory of, 258–259
 obstruction of, stroke from, 246
 posterior, 96f
 fetal origin of, 264–265
 infarction of, 264–265, 264f–266f
 vasculitis of, 271, 278f
Cerebral blood flow, in stroke, 279, 281, 282
Cerebral blood volume, in stroke, 279, 281, 282
Cerebral edema, 337, 339–340, 339f
 in brain tumors, 129, 130f, 132f
 malignant, 247–248
Cerebral hemispheres, 88, 89f
Cerebral hemorrhage
 cerebral infarction with, 248, 249f–251f, 252
 petechial, 248, 251f
 primary, 246
 space-occupying, 248, 250f
 with venous infarction, 268
Cerebral infarction, 246
 hypoxic-ischemic encephalopathy and, 271, 275f
 in cerebral hemorrhage, 248, 249f–251f, 252
 in meningeal tuberculosis, 220, 222f
 ischemic penumbra in, 281
 lacunar, 252, 254f
 meningeal enhancement in, 418, 419f
 parenchymal enhancement in, 252, 253f
 subacute, T2 fogging in, 248

Cerebral infarction (*Continued*)

toxin exposure and, 271
venous occlusion and, 265, 268, 271
Cerebral ischemia
 hemodynamic pathophysiology in, 279, 281
 stroke risk in, 246
Cerebral peduncle, 90, 95f, 96f
Cerebral vascular malformations, 291–302
Cerebral vein
 computed tomographic venography of, 271, 273f
 internal, 98f, 99f
 occlusion of
 infarction from, 265, 268, 271
 stroke from, 246
 thrombosis of, 268, 271, 272f
Cerebritis, 214
 central nervous system trauma and, 347, 347f
 early, 214, 215f
 late, 214, 215f
 magnetic resonance imaging of, 214, 219f
 tuberculosis and, 222
Cerebrospinal fluid, 87, 402
 in dura/arachnoid enhancement, 410
 in hydrocephalus, 345
 in meningeal neoplasm, 407
 in optic nerve-sheath complex tumors, 475
 in pia/subarachnoid space enhancement, 411
 meningeal neoplasm spread to, 425–426
 post-traumatic leak of, 346, 346f
Cerebrum
 arteriovenous malformation of. *See* Arteriovenous malformation, cerebral.
 atrophy of, 351
 vs. normal-pressure hydrocephalus, 357, 358f, 359, 359f
 infection of, 207–242
 magnetic resonance spectroscopy of, 390, 390f, 391f
 inflammation of, 207–242
Cervical adenopathy, 575–599
 evaluation of, 579–586
 anatomic principles of, 579–580, 581f–584f, 582–583
 lymph nodes in, 579–580, 581f
 masses in, 586, 586f, 587f
 nodal classification in, 582–583, 582f, 583f
 nodal staging in, 583–585, 584f, 585f
 unknown primary in, 585, 585f
 pediatric, 715, 716f, 717

Cervical fascia
 deep, 591, 593, 593f
 superficial, 591
Cervical nerve root, 751, 752f
 block of, 828
 posterior, 115f
 schwannoma of, 597, 598f
Cervical sinus, 651
Cervical space, posterior, third brachial apparatus anomaly in, 694
Cervical spine
 anatomy of, 751, 752f
 computed tomographic-guided biopsy of, 815, 816f
 decompression surgery on, 755, 758, 759f–760f, 760
 degenerative disease of, 751–760, 752f, 753b, 753f
 disk herniation of, 751
 disk space infection of, epidural abscess with, 808, 809f
 diskogenic stenosis of, 755, 756f, 757f–758f
 facet joint hypertrophy in, 754

Cervical spine (Continued)

facet joint injection of, 824, 825f, 826, 826f
foraminal stenosis in, 754, 755f
ligamentum flavum hypertrophy in, 754, 754f
multislice helical computed tomography of, 2261, 2262f
nondiskogenic stenosis of, 754–755, 754f–756f
osteomyelitis of, 808, 809f
osteophytosis of, 754–755, 754f
postoperative changes in, 755, 758, 759f–760f
spondylosis of, 751
stenosis of
 diskogenic, 755, 756f, 757f–758f
 nondiskogenic, 754–755, 754f–756f
 posterior longitudinal ligament ossification and, 755, 756f
uncinate processes of, 751, 752f
hypertrophy of, 754, 755f

Cervix, 1717f, 1718

cancer of, 1728–1730, 1784–1785, 1786f, 1787, 1787f
 computed tomography of, 1729, 1730f
 lymph node metastasis in, 1720–1721, 1721f
 metastatic, 1729, 1730f
 recurrent, 1729, 1730f
 staging of, 1728–1729, 1729t, 1785, 1786t, 1787
embryology of, 2079
endometrial carcinoma of, 1789
intraepithelial neoplasia of, 1728
magnetic resonance imaging of, 1762, 1762f
non-Hodgkin's lymphoma of, 1730, 1731f
pediatric, 2077

Chemical(s), percutaneous ablation with, 2245–2246, 2246f

Chemical shift, in magnetic resonance angiography, 53–54, 54f

Chemodectoma, 971

Chemotaxis, in peritoneal infection, 1615

Chemotherapy

disseminated necrotizing
 leukoencephalopathy from, 441, 442f
enteropathy from, 1476, 1476f, 1477f
liver biopsy and, 2180
mineralizing microangiopathy from, 441, 443f
pediatric
 bone marrow effects of, 2108, 2109f
 thymus regrowth after, 2008, 2008f
reversible posterior leukoencephalopathy syndrome in, 445–446
thymic enlargement after, 953, 955f
thymic rebound after
 multislice helical computed tomography of, 2271, 2271f
 pediatric, 2008, 2008f

Chest, pediatric

 computed tomography of, 1977t
 diseases of, 2000–2011

Chest pain, multislice helical computed tomography of, 2266t

Chest wall, 1002–1014

complications of, 2192–2193
contraindications to, 2188–2189, 2189f
cutting needles in, 2191–2192, 2191f
history of, 2128–2129
needles for, 2189
surgical implications of, 2192
technique for, 2189–2191, 2189f–2191f
tumor diagnosis with, 2192
tumor indications for, 2188
imaging of, 1407–1408
in cystic fibrosis, 1414, 1448–1449, 1449f, 2032, 2033f
in hemochromatosis, 1448, 1448f, 1449f
in von Hippel-Lindau disease, 1451, 1556, 1556f
insulinoma of, 1476–1478, 1478f
intraductal papillary mucinous neoplasm of, 1470–1471, 1470f–1473f
islet cell tumors of, 1475–1476, 1476f, 1477f
clinical syndromes with, 1454
lesser sac of, 2032
lymphangioma of, 1450
lymphatic drainage of, 1400
lymphoma of, 1469
magnetic resonance imaging of, 1401, 1403, 1403f, 1408, 1410–1411, 1410f, 1411f
magnetic resonance pancreatography of, 1412–1413, 1412f
malignant tumors of, 1454–1481
metastatic tumors of, 1480, 1480f
multislice helical computed tomography of, 2266, 2267f
nonendocrine tumors of, 1414, 1416f, 1417, 1417f, 1455–1462
biliary obstruction in, 1459–1460, 1461f
contrast enhancement in, 1459
density changes in, 1458–1459, 1458f, 1459f
ductal dilatation in, 1459, 1460f
in venous system, 1460, 1462, 1464f
liver metastases in, 1462
local extension of, 1460, 1462, 1462f–1464f
lymph nodes in, 1462
morphologic changes in, 1455–1457, 1456f–1458f
prognosis of, 1466–1467, 1468f
signs of, 1455
staging of, 1463, 1465–1467, 1465t, 1467f, 1468f
surgery for, 1463–1465
vs. other mass-like conditions, 1457–1458
vs. pancreatitis, 1467–1468
papillary neoplasms of, 1474–1475, 1475f
pediatric, 2032–2038
anatomy of, 2032
developmental abnormalities of, 2032
epithelial tumors of, 2037–2038, 2038f
hereditary diseases of, 2032–2033, 2033f
infection of, 2033–2036, 2034f–2036f
inflammation of, 2033–2036, 2034f–2036f
laceration of, 2036–2037, 2037f

Pancreas (Continued)

neoplasms of, 2037–2038, 2038f
non-epithelial tumors of, 2038, 2038f
non-Hodgkin's lymphoma of, 2038, 2038f
trauma to, 2036–2037, 2036f, 2037f
penetration of, in peptic ulcer disease,
1428–1429, 1429f
position of, 1400
postoperative evaluation in, 1480, 1481f
retention cyst of, 1422, 1423f, 1424f
short, 1405, 1407f, 1408
size of, 1398–1399
small bowel tumor involvement of, 1480
somatostatinoma of, 1479–1480
spurious mass of, 1407, 1407f
squamous cell carcinoma of, 1468, 1468f
tail of, torsion of, 1407, 1407f
transplantation of, 1414, 1415f
trauma to, 1447, 1447f, 1448f
tumors of, needle tract implantation of, 2139
ultrasonography of, 1407–1408, 1480–1481
vascular abnormalities of, 1451–1452,
1451f–1455f, 1454
vascular anatomy of, 1397–1398, 1397f,
1400
vipoma of, 1480
Pancreas divisum, 1405, 1405f, 203
Pancreatectomy, 1464–1465
Pancreatic carcinoma
biliary tract obstruction from, 1372, 1372f,
1373f
duodenal invasion in, 1434, 1434f
in common bile duct, 1377, 1377f
Pancreatic duct, 1399, 1400f, 1401f
calcification of, 1422, 1424, 1424f, 1425f
computed tomography of, 1421–1422
congenital variants of, 1404–1405, 1404f
disease differentiation in, 1426, 1427f,
1427t
gas within, 1424, 1425f
in chronic pancreatitis, 1446, 1447f
neoplastic changes of, 1424, 1426f
Pancreatic pseudocyst, 1437–1439, 1438f
aspiration of, 2193, 2206–2207
complications of, 1440, 1442f
computed tomographic-guided drainage of,
2205–2208, 2207f, 2208f
fistula in, 1443, 1443f
gas in, 1443–1444, 1443f
hemorrhage of, 1440, 1442f
image-guided drainage of, 2205–2208, 2207f,
2208f
infection in, 1443, 1443f
internal drainage of, 1445
location of, 1439–1440, 1440f, 1441f
magnetic resonance imaging-guided drainage
of, 2208, 2209f
natural history of, 1444
resolution of, 1440, 1441f
rupture of, 1440, 1442f
surgery for, 1444–1445
vascular problems in, 1444, 1444f
Pancreaticoduodenal veins, cancer of, 1460,
1462, 1464f
Pancreatitis, 1426–1427
acute
edematous, 1427–1428, 1428f–1430f
gastric thickening in, 1429, 1430f
ascitic fluid in, 1628
causes of, 1427
chronic, 1445–1447
calcification in, 1446, 1446f, 1447f
diagnosis of, 1445–1447, 1445f–1447f
vs. adenocarcinoma, 1428f–1430f,
1429–1430

Pancreatitis (Continued)

computed tomography of, 1422, 1423f,
1424f
duodenal involvement in, 1435, 1435f
edema in, 1427–1428, 1428f–1430f
vs. fluid collection, 1431
emphysematous, 1433–1436, 1434f–1436f
hemorrhage with, 1431
hereditary, 1447–1448, 1448f
infected vs. sterile necrosis in, 1432
infection in, 1433
inflammation evolution in, 1430–1433,
1431f, 1432t, 1433f, 1433t
magnetic resonance imaging of, 1413–1414,
1413f, 1414f
mass vs. neoplasm in, 1431
pediatric
acute, 2033–2035, 2034f, 2035f
enlargement in, 2034, 2034f
fluid collections in, 2034, 2034f,
2035f
mesenteric fat infiltration in, 2035,
2035f
necrosis in, 2033, 2034, 2034f
pseudocyst in, 2033, 2035, 2035f
chronic, 2035–2036, 2036f
prognostic indicators for, 1432–1433
pseudoaneurysm in, 1444, 1444f
severe necrosis, 1431–1432, 1431f
staging of, 1432, 1432t, 1433t
vs. pancreatic cancer, 1467–1468
Panencephalitis, subacute sclerosing, 213
Papillary tumors
pancreatic, 1474–1475, 1475f
peritoneal, 1651, 1651f
Papilloma
choroid plexus, 150, 152f
fungiform, 563
sinonasal cavity, 563, 565f
Papillomatosis, tracheolaryngeal, 889–890, 890f
Paracentral lobule, 107f

Paraganglioma, 531
cervical, 594–595, 596f
glomus jugulare, 531, 532f–533f
mediastinal, 971, 972f
pediatric, 2057
retroperitoneal, 1696–1697
spinal, 778
Paraglottic space, 603, 604f, 605f
supraglottic tumor spread into, 607, 607f
Paragonimiasis, intracranial, 234
Paragonimus westermani, 234
Parahippocampal gyrus, 95f, 98f, 104f, 108f
Parametrium, 1718, 1718f
Paranasal sinuses
Aspergillus infection of, 562
carcinoma of, 566f
computed tomography of, 556, 557f, 558,
558f
fungal disease of, 561, 561b
granulomatous disease of, 562–563, 563f
hemorrhage of, vs. sinusitis, 559
in common cold, 559
magnetic resonance imaging of, 558–559,
559f
mucocoeles of, 563, 564f, 565f
mucormycosis of, 230, 561
odontogenic tumors of, 571, 571f
osteopetrosis of, 570f, 571
ostia for, 553
syndromes affecting, 570b
unilateral opacification of, 559, 560b
Parapharyngeal space, 623–624, 624–625t
prestyloid
benign mixed salivary gland tumor in,
652, 653f

Parapharyngeal space (Continued)

benign tumors of, 652–653, 653f
congenital lesions of, 651
infection of, 651–652, 652f
inflammation of, 651–652, 652f
lesions of, 651–653, 652f, 653f
lipoma of, 652–653
malignant tumors of, 653
pleomorphic adenoma in, 652, 653f
pseudotumor of, 651
Paraplegia, celiac nerve block and, 2243, 2244f
Pararectal space, 1623
Pararenal space, 1624, 1625f
abscess of, percutaneous drainage of, 2232
anterior
abscess of, 1638, 1639f
fluid in, 1658, 1658f
pancreas in, 2032
posterior, 1657, 1657f
abscess of, 1638, 1639f, 1640f
fluid in, 1658, 1658f
Parasitic infection
biliary tract, 1366–1367, 1367f
cerebral, 231–242
Paraspinous mass, computed tomographic
biopsy of, 815, 817f
Parathyroid glands, 681–687
adenoma of, 684, 684f, 685f
angiography of, 687, 687f
carbon 11 methionine PET imaging of,
686
ectopic, 961, 961f, 962f
hyperparathyroidism from, 683
carcinoma of, 687
computed tomography of, 683, 683f
cyst of, 687
hyperplasia of, 684, 686f
imaging of, radiopharmaceutical choice in,
682, 682f
magnetic resonance imaging of, 683
pathologic conditions of, 683–687
ultrasonography of, 682–683
Parietal lobe, 88, 105f, 106f, 108f
Parieto-occipital fissure, 99f, 101f, 106f
Parieto-occipital sulcus, 88, 89f
Parkinsonian syndromes, 394
Parkinson's disease, 363
Parkinson's plus syndrome, 364
Parotid space, 622, 626f

Pars tensa membranae tympani, perforation of,
520, 522f
Parsonage-Turner syndrome, 1965–1966
Passavant's ridge, 620
Patellar ligament, injury of, 1895–1896
Patellofemoral joint
dislocation of, 1897
instability of, 1896–1897, 1897f
Pectus carinatum, 2011
Pectus deformity, 2010f, 2011
Pectus excavatum, 2011
Pedicles, 111, 112f, 120f
Peliosis, splenic, 1498–1499
Pelizaeus-Merzbacher disease, 387, 453, 455,
455f
Pelvic floor relaxation, 1795, 1796f
Pelvic inflammatory disease, 1733–1734,
1734f, 1781, 1782f
pediatric, 2086, 2086f
Pelvic muscles, pediatric, 2078–2079
Pelvimetry, computed tomographic, 1743–1744
Pelvis, 1715–1745
abscess of, 1637–1638, 1639f
computed tomographic drainage of,
1740–1741, 1741f, 1742f

Pelvis (Continued)

percutaneous drainage of, 2232, 2233f–2235f
after cystectomy, 1738–1739, 1739f
after radiation therapy, 1739–1740, 1739f, 1740f
after resection, 1738–1739, 1738f, 1739f
anatomy of, 1715–1719, 1715f–1718f
anterior, 1621–1622
blood supply of, 1715f, 1716–1717, 1716f
cancer of, 1721, 1738
computed tomographic-guided biopsy of, 2201–2203, 2202f, 2203f
computed tomography of, 1715–1745
congenital anomalies of, 2079–2081
cystic teratoma of, 1753, 1754f
extraperitoneal spaces of, 1719
false, 1715
female
benign conditions of, 1776–1782
evaluation of, 1776–1792
magnetic resonance imaging anatomy of, 1760, 1761f, 1762
malignancies of, 1784–1792
obstetric conditions of, 1782, 1784, 1784f
fistula in, radiotherapy and, 1793, 1794f
fluid collections in, 1740–1742, 1741f, 1742f
fracture of, 1742, 1743f, 1744f
hematoma of, 1742, 1742f
lipomatosis of, 1745
lymph nodes of, 1717, 1717f
metastasis to, 1720–1721, 1720f, 1720t, 1721f
lymphangioma of, 1742
lymphocele of, 1741, 1742f
magnetic resonance angiography of, 1755–1757, 1757f
magnetic resonance imaging of, 1751–1796, 1752f, 1753t, 1754f–1756f
magnetic resonance venography of, 1757–1758, 1758f, 1759f
male
benign disorders of, 1763–1766, 1765f, 1766f
magnetic resonance imaging anatomy in, 1758, 1759f–1761f, 1760
malignancies of, 1766–1771, 1767f, 1769f–1772f
muscles of, 1715–1716, 1716f
musculoskeletal problems of, 1742–1744, 1743f, 1744f
pediatric, 2075–2093
abscess of, 2089–2090
adnexal masses of, 2085–2086, 2086f
anatomy of, 2076–2079
computed tomography of, 2075, 2075t
female, 2076–2077, 2077f, 2078f
hematoma of, 2090
magnetic resonance imaging of, 2075–2076
male, 2078–2079, 2078f
masses of, 2082, 2089–2090, 2090f
posterior, 1622–1623
postoperative complications in, 1792–1793, 1794f–1796f, 1795
post-treatment mass in, 1740
presacral tumors of, 2090, 2091f, 2092, 2092f
pyomyositis of, 1741, 1742f
radiation therapy of
complications of, 1792–1793, 1794f–1796f, 1795
fistulas from, 1738, 1738f
recurrent carcinoma of, vs. postoperative fibrosis, 1793, 1795f

Pelvis (Continued)

soft tissue tumors of, 1742
spaces of, 1621–1623
true, 1715
ureters in, 1717, 1717f
Pelvocalyceal neoplasms, 1577, 1579–1581, 1579f–1581f
Pentamidine, for *Pneumocystis carinii* pneumonia, 869
Peptic ulcer disease
benign, 1428, 1428f
penetration in, 1428–1429, 1429f
Perfusion studies, multislice helical computed tomography in, 2265, 2265f
Pericardiacophrenic vein, 1063, 1066f, 1067f
Pericardial effusion, 1081
causes of, 1083t
computed tomography of, 1081, 1082f–1083f
magnetic resonance imaging of, 1094–1095, 1095f, 1096f, 1097
Pericardial recess, superior, 946, 946f
Pericardial tamponade, 1096
Pericarditis, constrictive, 1084f, 1085
Pericardium
acquired disease of
computed tomography of, 1080–1081
magnetic resonance imaging of, 1093–1094, 1095f, 1096, 1096f
anatomy of, 1092
appendages of, 1092
computed tomography of, 1080–1086
congenital absence of, 1092–1093, 1093f
congenital defects of, 1080
constriction of, 1096–1097, 1097f
cyst of, 968, 969f
computed tomography of, 1081, 1081f
in middle mediastinum, 967–968, 968f, 969f
magnetic resonance imaging of, 1093
diseases of, 1092–1098
in right ventricular dysfunction, 1115
diverticulum of, 1093, 1094f
mesothelioma of, 1085, 1086f
metastases to, 1085, 1085f, 1097
pediatric, masses of, 1993–1994, 1996, 1996f
preaortic recess of, 1092
retroaortic recess of, 1092, 1093f
sarcoma of, 1097–1098, 1098f
superior recess of, 1092, 1093f
thickening of, 1094, 1096, 1096f
in pleural mesothelioma, 1097, 1098f
tumors of
computed tomography of, 1085, 1085f, 1086f
magnetic resonance imaging of, 1097–1098, 1098f
visceral, 1092
Pericolic space, 1616, 1617f–1621f, 1621
abscess of, 1636, 1638f
percutaneous drainage of, 2230
Perihepatic space, 1616, 1617f–1623f
Perihippocampal fissure
in Alzheimer's disease, 352f–354f, 353, 355, 357, 358f
in normal-pressure hydrocephalus, 357, 358f, 359, 359f
Perimesencephalic cistern, 90, 95f
in brain swelling/edema, 339, 339f

infection of, 2068–2069, 2068f, 2069f
inflammation of, 2068–2069, 2068f, 2069f
metastases to, 2069, 2069f
neoplasms of, 2069, 2069f
trauma to, 2070–2071, 2070f
pelvic spaces in, 1621–1623, 1624f
pericolic spaces of, 1616, 1617f–1621f, 1621
perihepatic spaces of, 1616, 1617f–1623f
reflection of, 1625
supracolic space of, 1616
visceral, 2067
Peritonitis, 1627–1629, 1627f, 1628f
Clostridium in, 1629
granulomatous, 1629, 1629f
in intestinal tuberculosis, 1443
pediatric, 2068, 2069, 2069f
tuberculous, 1629, 1629f
Periureteric venous ring, 1678, 1679f
Perivascular space
anatomy of, 402, 402f
cryptococcosis of, 409, 412f
vs. small-artery infarction, 252, 255f
Periventricular edema, in communicating hydrocephalus, 357

Perivertebral space, 622, 626t
Peroneus brevis tendon
 magnetic resonance imaging of, 1842f, 1843f, 1850, 1852, 1853f
 tear of, 1852, 1853f–1854f
Peroneus longus tendon, magnetic resonance imaging of, 1842f, 1843f, 1850, 1852, 1853f
Persistent pulmonary interstitial emphysema, 2001f, 2002
Petro-occipital fissure, 497f
Petrosal nerve, 500f, 501f
Petrous apex, 497f, 501f
 cholesterol granuloma of, 537, 539f
 epidermoidoma of, 535, 537f
Petrous bone, 93f
Pharyngeal aponeurosis, 622–623
Pharyngeal mucosal space, 623, 624t
 benign tumors of, 636–639
 congenital lesions of, 634, 634f
 inflammatory conditions of, 634–636, 635f, 636f
 juvenile angiofibroma of, 636–638, 637f, 638f
 lesions of, 633–648
 malignant tumors of, 639–648
 non-Hodgkin's lymphoma of, 648
 peritonsillar abscess of, 636
 postinflammatory dystrophic calcification of, 636, 637f
 postinflammatory retention cyst of, 636
 pseudomass of, 633
 squamous cell carcinoma of, 639–647
 Tornwaldt's cyst of, 634, 634f
Pharyngeal recesses, asymmetry of, 633
Pharyngobasilar fascia, 622–623
Pharyngocele, 599
Pharynx, 619, 620f, 628f
Phase
 in magnetic resonance angiography, 51, 52f, 53, 53f
 motion effects on, 56, 59
Phase contrast, in magnetic resonance angiography, 61, 62f
Phenylketonuria, 461
 magnetic resonance spectroscopy of, 386
Pheochromocytoma
 adrenal, 1519f–1522f, 1520–1521
 ectopic, 1520
 pediatric, 2057, 2088
 recurrent, 1521, 1522f
 with von Hippel–Lindau disease, 1555, 1556, 1557f
Phleboliths, 1816
 in gastric hemangioma, 1427
Phrenicocolic ligament, 1626
Phrygian cap, 1344, 1344f
Phthisis bulbi, 479, 489, 491, 491f
Physis, premature fusion of, 2116–2117, 2116f
Pia mater, 87
 abnormalities of, 38f, 407
 anatomy of, 401, 401f, 402f
 hematogenous tumor spread via, 426
 magnetic resonance imaging of, 409, 409f, 411, 412t, 413f, 414t
Pick's disease, 359, 386
Pigmented villonodular synovitis, 1818, 1820f
 ankle/foot, 1863
 hip, 1914–1916, 1915f
 knee, 1901–1902, 1903f, 1904f
 pediatric, 2112
 shoulder, 1964–1965
Pilon fracture, 1831, 1832f
Pineal gland, 97f, 99f, 100
 calcification of, 109
 germinoma of, 182, 182f

Pineal gland (*Continued*)
 parenchyma of, tumors of, 157–159, 158f, 159f
Pinealoma, third ventricular obstruction by, 357
Pineoblastoma, 158–159, 158f
 meningeal dissemination in, 423, 423f
Pineocytoma, 159, 159f
Piriform sinuses, tumor of, 610–611, 611f
Piriformis muscle, 1716, 1716f
Pitch, 7, 7t
 naming conventions for, 12, 12f
Pitch factor, 7, 7t
Pituitary gland, 104f, 107f
 adenoma of, 184–189
 contrast computed tomography of, 91–92
 macroadenoma of, 188–189, 188f–190f
 microadenoma of, 184–188, 186f, 187f
 nonneoplastic inflammatory conditions of, 187
Pixels, 2, 4f, 37
Plantar fasciitis, 1857–1858, 1860f
Plantar fibroma, 1862–1863, 1862f
Plantaris tendon, 1845
Plasmacytoma, 766
 gastric, 1425–1426, 1426f
Platelets, in image-guided microsurgery, 2141
Pleura, 997–1002
 asbestos-related disease of, 1001, 1002f
 benign fibroma of, 1000–1001, 1001f
 complications of, in pediatric pneumonia, 2004
 computed tomographic–guided biopsy of, 2169–2170
 computed tomography of, 997
 disease processes in, 997–998
 in liver biopsy, 2183
 magnetic resonance imaging of, 997
 malignant mesothelioma of, 1001–1002, 1002f, 1003f
 masses of
 benign, 1000–1001, 1001f, 1002f
 malignant, 1001–1002, 1002f, 1003f
 metastases to, 1002, 1002f
 in non–small-cell lung cancer, 914, 916f
 rounded atelectasis of, 1001, 1001f
 thymoma metastases to, 957, 958f
Pleural air, 1000, 1000f
Pleural effusion, 998–999
 chylothorax in, 999
 diaphragm sign in, 998, 998f
 displaced crus sign in, 998, 998f, 999f
 empyema in, 999, 1000f
 hematoma in, 999f
 hemothorax in, 998–999, 999f
 interface sign in, 998, 998f
 percutaneous drainage of, 2231
 split-pleura sign in, 999
Plummer's disease, 676
Pneumatocele, 2003, 2003f
Pneumatosis intestinalis, 1499, 1499f
 after transplantation, 1456, 1456f
 in strangulated small intestinal obstruction, 1463, 1464f
Pneumocephalus, 319, 319f
 tension, central nervous system trauma and, 347
Pneumocystis carinii infection
 retroperitoneal lymphadenopathy with, 1693
 splenic, 1498, 1498f
Pneumonia
 bronchiolitis obliterans organizing, 847, 850–851, 850f–852f
 cytomegalovirus, 860
 fungal, 2005, 2006f
 image-guided microsurgery of, 2176

Pneumonia (*Continued*)
 lipoid, 845
 pediatric
 cavitary necrosis in, 2003, 2004, 2004f, 2005f
 complications of, 2003–2004, 2004f, 2005f
 in immunocompromise, 2004–2005, 2006f
 parapneumonic effusions in, 2003
 persistent symptoms in, 2003
 pneumatocele in, 2003, 2003f, 2004, 2004f
Pneumocystis carinii
 bullae in, 871, 872f
 computed tomography of, 867, 868f–872f, 869, 871
 cystic, 869, 870f
 disseminated, 869, 871f
 ground glass opacity in, 860, 861f, 862f
 ground-glass infiltrates in, 867, 868f–869f
 mosaic attenuation patterns in, 860
 pentamidine for, 869
 solitary pulmonary nodule in, 869
 spontaneous pneumothorax in, 871
Pneumonitis, 860, 862f
Pneumopericardium, 1081
Pneumothorax
 in computed tomographic–guided biopsy, 2167–2168, 2168f, 2179
 in lung biopsy, 2167–2168, 2168f
 in lymphangiomyomatosis, 887f
 spontaneous, in *Pneumocystis carinii* pneumonia, 871
POEMS syndrome, disseminated Castleman's disease with, 979–980
Polyangiitis, microscopic, gastrointestinal, 1472, 1472f
Polyarteritis nodosa
 gastrointestinal, 1471–1472, 1472f
 renal hemorrhage with, 1590, 1590f
Polychondritis, laryngeal, 618
Polycystic kidney disease, 1284, 1285f, 1547
 abscess with, 1643
 autosomal dominant, 1548–1549, 1549f–1552f, 1551
 autosomal recessive, 1548, 1548f
 congenital hepatic fibrosis related to, 2014, 2014f
 infantile, 2052
 pancreatic pseudocyst in, 1442f
 pediatric
 autosomal dominant, 2053, 2053f
 autosomal recessive, 2052–2053, 2052f
 vs. renal cysts, 2050, 2051, 2051f
Polycystic liver disease, 1284, 1284f, 1285
Polycystic ovarian syndrome, 1762, 1764f, 2083
Polymorphonuclear leukocyte, 806
Polyp(s)
 angiomatous, vs. juvenile nasopharyngeal angiofibroma, 710
 antrochoanal, 653–654
 colonic, 1478
 endometrial, 1778, 1780f
 esophageal, 1401–1403
 gastric, 1426, 1427f
 in Behçet's syndrome, 1474, 1475f
 nasal, 559, 560f
 small intestinal, 1442, 1442f
 spenochoanal, 654
Polysomnography, overnight, in obstructive sleep apnea syndrome, 655
Polysplenia, 2025, 2025f
 inferior vena cava interruption in, 986f, 987
Pons, 89, 90f, 94f, 107f, 121f
 diffuse axonal injury to, 337, 339f
 imaging of, 92, 94f

Pons (Continued)

lesion vs. infarction of, 252, 256f
myelinolysis of, 448, 448f, 449f
Pontine cistern, subarachnoid hematoma in, 332–333, 333f
Pontine perforator artery, infarction of, 265
Popliteal cyst, 1898, 1898f
Popliteal fossa, synovial sarcoma of, pediatric, 2103, 2103f
Popliteal tendon, 1871, 1873f, 1874, 1875f
trauma to, 1888
Porencephaly, in central nervous system trauma, 345
Porta hepatis, 1318
gallbladder cancer to, 1358, 1358f
Portal hypertension, splenomegaly from, 1500, 1500f, 1501f
Portal vein, 1318
abnormalities of, 1454, 1454f
cavernous transformation of, 1452, 1453f, 1454
biopsy of, 2194
in hepatic metastases, 1298, 1300f
pancreas and, 2032
thrombosis of, 1332, 1454, 1455f
in choriocarcinoma, 1380, 1381f
in gastric carcinoma, 1421
pediatric, 2019–2020, 2020f
Porus acusticus, 496
Positron-emission tomography, in computed tomographic-guided procedures, 2134
Postcentral gyrus, 99f, 101f, 102f, 105f, 108f
Postcentral sulcus, 88, 89f, 104f
Posterior commissure, 89
Posterior fossa
anatomy of, 89–90, 90f
arachnoid cyst of, 537
contusion in, 335, 335f
epidural hematoma of, 324
in acoustic schwannoma, 529
infarction of, 265, 266f–269f
nasopharyngeal carcinoma spread to, 642–643
sectional imaging at, 92, 93f–97f, 97
Posterolateral fissure, 90
Postnasal space, basal cephalocele in, 654, 654f
Post-transplant lymphoproliferative disorder, pediatric, 2021
Post-tympanum, 495–496
Pott's puffy tumor, 403f
Pouch of Douglas
drop metastasis into, 2069, 2069f
peritoneal abscess in, 2068, 2068f
Precentral gyrus, 99f, 101f, 102f, 105f, 108f
Precentral sulcus, 88, 89f
Precuneus, 106f, 107f
Prepiglottic space, 603
oropharyngeal carcinoma infiltration of, 647
supraglottic carcinoma in, 607
Pregnancy
adnexal masses in, 1782, 1783f
pelvic evaluation in, 1782, 1784, 1784f
Premesencephalic cistern, 108f
Prepontine cistern, 116f, 121f
Presacral space
after radiation therapy, 1739–1740, 1740f
in ulcerative colitis, 1490
pediatric
chordoma of, 2092
lipomenigocele in, 2092
lymphoma of, 2092
meningocele in, 2092
myelomeningocele in, 2092
neuroblastoma in, 2090, 2091f, 2092, 2092f

Presacral space (Continued)

neurogenic tumors in, 2090, 2091f, 2092, 2092f
teratoma in, 2090, 2091f
Prestyloid parapharyngeal space, 624, 624t
Pretracheal space, 945, 945f
Prevascular space, 945, 945f
Prevertebral muscle, oropharyngeal carcinoma invasion by, 647–648
Primary fissure, 90
Primitive neuroectodermal tumor
pediatric, 2097, 2098f
spinal, 778
Prion, in Creutzfeldt-Jakob disease, 362
Progressive supranuclear palsy, 364
Prolactinoma, pituitary, 184–185
Proptosis, 475
juvenile nasopharyngeal angiofibroma and, 637
Prostate cancer, 1724, 1768–1770, 1769f–1771f
capsular penetration by, 1768, 1769f–1771f, 1770
choriocarcinoma in, 1381f
computed tomography of, 1724–1726, 1725f
magnetic resonance imaging of, 1769–1770, 1769f–1771f
orbital metastases in, 484, 486f
retroperitoneal lymph node metastases in, 1690–1691, 1691f
seminal vesicle invasion in, 1770, 1771f, 1772, 1772f
spinal metastases in, 765
staging of, 1724, 1725t, 1768
temporal bone metastases in, 544f
treatment of, 1768–1769
Prostate gland, 1717f, 1718, 1718f
abscess of, 1766
anterior fibromuscular stroma of, 1758, 1759f
benign hyperplasia of, 1758
central, 1758
magnetic resonance imaging of, 1758, 1759f, 1760, 1760f
pediatric
magnetic resonance imaging of, 2078, 2078f
rhabdomyosarcoma of, 2086–2088, 2087f
peripheral zone of, 1758
Prostate-specific antigen (PSA), 1724
Prostatitis, 1765–1766, 1766f
Prosthetic grafts, computed tomographic-guided aspiration of, 2209–2210, 2210f, 2211f
Protease inhibitors, urinary tract stones from, 1600, 1602f
Protein, in magnetic resonance spectroscopy, 376
Proteinosis, alveolar, 860, 861f, 864
Proton, magnetic properties of, 37, 38f
Proton density, 92
Proton echoplanar spectroscopic imaging, 394–395
Protympanum, 495, 498f, 510f
Pseudoachalasia, 1411
Pseudoaneurysm, 342
aortic, after coronary artery bypass, 941, 942f
computed tomography of, 937, 939f
dissecting, 286
in pancreatitis, 1444, 1444f
left ventricular, 990, 990f
of saphenous vein graft, 1074, 1075f
postoperative, 1058, 1058f
splenic artery, 1451
ventricular, 1072–1073, 1073f

Pseudocyst

adrenal, 1530–1531, 1531f
in acute pediatric pancreatitis, 2033, 2035, 2035f
mediastinal, with chronic pancreatitis, 965, 966f
pancreatic. *See* Pancreatic pseudocyst.
Pseudodiverticulosis, esophageal intramural, 1410
Pseudomass, of pharyngeal mucosal space, 633
Pseudomembranous colitis, pediatric, 2063, 2064f
Pseudomeningocele, lumbar, postoperative, 748, 748f
Pseudomonas, in malignant external otitis, 523, 524f
Pseudomyxoma peritonei, 1654
with appendiceal mucinous cystadenocarcinoma, 1486, 1487f
Pseudopapilledema, 489
Pseudothrombus, inferior vena caval, 1680, 1682f
Pseudotumor
inflammatory, splenic, 1507–1508
lacrimal gland, 489, 490f
orbital, 481, 482f
retropharyngeal space, 648
Pseudo-Whipple's disease, 1446
Psoas compartment, retroperitoneal, 1657, 1657f
Psoas muscle, 110f, 112f, 114f, 1715, 1715f
Pterygoid laminae, in juvenile nasopharyngeal angiofibroma, 637
Pterygopalatine fossa, juvenile angiofibroma of, 637, 637f, 709
Pulmonary. *See also* Lung(s).
Pulmonary artery
anomalies of, 1991, 1992f, 1993f
atresia of, central shunt in, 1993, 1994f
computed tomography of, 1064f
dilatation of, 1129
in congenital heart lesions, 1991, 1992f, 1993f
in right ventricular outflow obstruction, 1129
left, 946, 946f, 947f, 949f, 1120, 1121f, 1991, 1992f
magnetic resonance imaging of, 1127, 1128f, 1129, 1129f
main, 947f
right, 946, 946f, 947f, 949f, 1120, 1121f
stenosis of, 1128f
Pulmonary edema, 860, 864
Pulmonary embolism, multislice helical computed tomography of, 2265–2266, 2266f
Pulmonary hypertension, 1117
in mitral stenosis, 1108, 1109f, 1115
in right-sided heart failure, 1115
magnetic resonance imaging of, 1115, 1116f
tricuspid regurgitation from, 1117
Pulmonary outflow tract, 947
Pulmonary stenosis, congenital, 1129, 1130f
Pulmonary valve
atresia of, in tetralogy of Fallot, 1135, 1135f, 1991, 1993f
stenosis of, 1069
Pulmonary vascular occlusive disease, 1117
Pulmonary vascular resistance, in right ventricular dysfunction, 1115
Pulmonary vein
computed tomography of, 1064f, 1065f
left superior, 947, 947f
right superior, 946, 946f, 947, 947f
Pulmonary veno-occlusive disease, acquired, 1115

Pulmonary venous connections, 1991, 1993f
Pulmonic stenosis, supravalvular, pulmonary arteries in, 1129, 1129f
Pulses, saturation, 61, 61f
Putamen, 95f, 97f, 98f, 104f
Pyelonephritis
bacterial, 1582, 1582f, 1583f

thrombosis of, indwelling catheter and, 988f
Subcutaneous fat, 116f
Subdiaphragmatic space, abscess of, 1634, 1634f–1636f, 1635
Subdural effusion, 208
Subdural empyema, 208, 209f, 210f
Subdural hematoma, 326–332
acute, 326, 326f, 327f
brain injury with, 326

Subdural hematoma (*Continued*)

- causes of, 326
- chronic, 328, 330, 330f, 331f
 - vs. chronic subdural hygroma, 330, 332, 332f
- hypodensity of, 326, 327f
- in child abuse, 344, 344f
- interhemispheric, 326, 328, 328f
- isodense, 328, 329f
- location of, 326, 327f
- magnetic resonance imaging of, 330, 331f, 332f
- near tentorium, 326, 327f
- postoperative, 328, 329f
- subacute, 330, 331f, 402
- vs. epidural hematoma, 324, 325f
- Subdural space, 401
- Subependymoma, 150, 151f
- Subglottis, 601, 604f
 - vocal cord lesion extension to, 609f
- Subhepatic space, 1616, 1617f-1623f
 - abscess of, 1634-1635, 1635f
 - percutaneous drainage of, 2227, 2228f, 2229f
- Sublabral recess, glenoid, vs. tear, 1958, 1960, 1960f
- Sublingual space, 622
- Submandibular gland, 577f, 578
- Submandibular space, 622
 - anomalies of, 694
 - second branchial cleft cyst of, 651
- Subphrenic space, 1616, 1617f-1623f
 - abscess of, percutaneous drainage of, 2226-2227, 2227f-2228f
 - ascitic fluid in, 1628, 1628f
 - hematoma of, 1629, 1630f
 - post-traumatic hemorrhage into, 1631, 1632f
- Subscapularis tendon, 1940
 - tear of, 1952
- Substantia nigra, 95f
- Sulcal effacement, in communicating hydrocephalus, 357
- Sulfatides, in white matter, 451
- Superior fissure, 106f
- Superior longitudinal fasciculus, 89
- Superior recess, 1616, 1619f-1621f
- Superior rectus-levator palpebrae superioris complex, 477f, 478f, 479f
- Supracolic space, 1616, 1617f-1623f
- Supraglottis, 601, 604f, 605f
 - laryngectomy of, 605, 605f, 606b
 - partial laryngectomy of, 607-608
 - tumors of, 605-608, 605f-608f, 606b, 610f
- Suprahyoid head/neck region. *See also*
 - Nasopharynx; Oropharynx.
- classification of, 619-620, 620f
- deep fascia of, 621-624
 - buccopharyngeal, 622
 - cloison sagittale of, 622
 - danger space of, 622
 - deep layer of, 622
 - masticator space of, 622, 625t
 - middle layer of, 622-624
 - muscular space of, 622
 - parapharyngeal space in, 623-624, 624t
 - parotid space of, 622, 626t
 - perivertebral space of, 622, 626t
 - pharyngeal mucosal space in, 623, 624t
 - pharyngobasilar, 622-623
 - prestyloid parapharyngeal space in, 624, 624t
 - retropharyngeal space in, 623, 625t
 - retrostyloid parapharyngeal space in, 624, 625t

Suprahyoid head/neck region (*Continued*)

- sublingual space of, 622
- submandibular space of, 622
- superficial layer of, 621-622
- suprasternal space of, 622
- tensor veli palatini in, 622
- divisions of, 619, 620f
- imaging of
 - anatomy for, 626, 627f-632f
 - techniques for, 626, 631-633
- spatial approach to, 620-624, 621f, 624t-626t
 - superficial fascia of, 621
- Supramarginal gyrus, 101f, 102f, 105f
- Suprascapular artery, 1940
- Suprascapular nerve, 1940
 - dysfunction of, 1965, 1965f

 Fracture.
 abdominal, blunt, 1452–1453, 1453f, 1454f
 aortic. *See* Aorta, trauma to.
 biliary, 1383, 1384f
 bladder, 1744–1745
 central nervous system. *See* Central nervous system, trauma to.
 deceleration, aortic trauma in, 1048
 duodenal, 1434–1435, 1435f

Trauma (*Continued*)
 esophageal, 1412–1413, 1413f
 facial, 572f, 573
 foot, 1829–1831, 1830f, 1831f
 hip, 1920–1924, 1921f–1924f
 laryngeal, 613, 616, 616f, 617f
 lower urinary tract, 1744–1745, 1744f, 1745f
 orbital, 478–479, 480f, 572–573, 572f
 pancreatic, 1447, 1447f, 1448f
 pediatric, 2114–2117, 2114f–2116f
 growth plate arrest in, 2116–2117, 2116f
 hepatic, 2019, 2019f
 pulmonary evaluation in, 2005–2006, 2006f
 renal, 2053–2054, 2053t, 2054f
 renal, 1587–1588, 1587f–1589f
 shoulder, 1966–1968, 1966f–1968f
 sinonasal, 572–573, 572f, 573f
 small intestinal, 1452–1453, 1453f, 1454f
 spinal cord, 783, 784f
 splenic. *See* Spleen, trauma to.
 temporal bone, 540, 547
Treacher Collins syndrome, 556
Treponema pallidum, 227
Trevor's disease, 2100
Triangular ligament, 1625–1626
Tricuspid valve
 atresia of, 1124f
 in tetralogy of Fallot, 1135, 1136f
 regurgitation at, 1068–1069, 1069f
 differential diagnosis of, 1113–1114
 magnetic resonance imaging of, 1112–1114, 1113f
 pulmonary hypertension and, 1117
 stenosis of, 1068
Trigeminal nerve, schwannoma of, 536
Trigger-point injections, spinal, 828, 828f
Trigone, 98f, 99f
Trimalar fracture, 572f, 573
Triplane fracture, 1831, 1833f
Tropheryma whippelli, 1448–1449
Trousseau's sign, 1454
Truncus anterior, 946, 946f
Tuberculoma
 intracranial, 390
 intramedullary, 796
 meningeal, 220, 222, 223f, 224f, 414, 416f
Tuberculosis
 adrenal, 1531, 1531f
 cerebritis in, 222
 cervical adenopathy in, 586, 586f
 colitis in, 1489–1490, 1489f
 esophageal, 1410, 1411f
 in peritonitis, 1629, 1629f
 intestinal, 1442–1443, 1443f, 1444f
 vs. Crohn's disease, 1399
 intramedullary, 796
 meningeal, 220–224, 414–415, 416f
 cerebral infarction in, 220, 222f
 cisterns in, 220, 221f
 computed tomography of, 220, 221f–223f, 222
 magnetic resonance imaging of, 222, 223f, 224f
 paranasal sinus, 563
 pulmonary, 878–879
 aspergilloma in, 877f, 878
 bronchogenic spread of, 864, 864f, 872, 875f, 876f
 cavitation in, 872, 875f
 chronic fibrocific, 872, 876f
 computed tomography of, 872, 875f–878f, 878
 Ghon's lesion in, 878
 in acquired immunodeficiency syndrome, 877f, 878–879, 878f

Tuberculosis (*Continued*)
 Ranke's complex in, 876f, 878
 Simon's foci in, 877f, 878
 renal, 1586–1587, 1586f, 1587f
 small intestinal, 1443, 1444f
 spinal, 806, 808–809, 811f
 splenic, 1642, 1643f
Tuberous sclerosis
 angiomyolipoma with, 1575, 1577f, 1578f
 pediatric, 2050–2051, 2051f
 hepatic/renal angiomyolipoma with, 1280f, 1281
Tuberous sclerosis complex, renal, 1556–1557, 1557f, 1558f
Tubo-ovarian abscess, 1781
 pediatric, 2086, 2086f
Tumoral calcinosis, shoulder, 1964
Tympanic cavity, 495–496, 502f, 503f
Tympanic membrane, perforation of, 520, 521f
Tympanic ring, 507f
Tympanic sinus, 499f, 505f, 509f
Typhlitis, neutropenic, pediatric, 2063–2065, 2065f

Ulcer(s)
 aortic, penetrating atherosclerotic, 1669
 decubitus, sinus tracts with, 1920, 1921f
 penetrating, pancreatic gas from, 1435
Ulcerative colitis, 1490–1491, 1490f, 1491f, 1649
 bowel perforation in, 1490, 1491f
 bowel wall thickening in, 1490, 1490f
 carcinoma in, 1490, 1491f
 in colorectal carcinoma, 1490, 1491f
 pediatric, 2062, 2063f
 toxic megacolon in, 1490, 1491f
 vs. Crohn's disease, 1487
Ultrasonography, liver biopsy via, 2179
Uncinate process
 cervical, 751, 752f
 hypertrophy of, 754, 755f
 variations of, 560
Uncovertebral joint, 119
Urachus, pediatric
 anomalies of, 2088–2089
 cyst of, 2089, 2089f
Urea cycle enzyme errors, 461
Ureter(s)
 circumcaval, 1678, 1679f
 ectopic, pediatric, 2040–2041, 2041f
 neoplasms of, 1581, 1582f
 obstruction of
 calculi in, 1599–1600, 1599f–1601f
 urinoma from, 1601, 1603f
 pelvic, 1717, 1717f
 retrocaval, 1678, 1679f
 transitional cell carcinoma of, 1581, 1582f
Ureteral bud, atresia of, 2053
Ureteropelvic junction
 calculus of, 1579, 1580f
 congenital obstruction of, 1579, 1580f
 trauma to, 1588
Urinary bladder. *See* Bladder.
Urinary tract
 calculi in, 1598–1600, 1599f–1602f
 trauma to, 1744–1745, 1744f, 1745f
Urinoma, 1601, 1603f, 1604f
 collecting system disruption and, 2054
 perinephric, pediatric, 2054f
Urokinase, in percutaneous abscess drainage, 2222, 2222f, 2222t, 2223t, 2224t

- Urolithiasis, 2044–2045
- Urothelial cancer
 hydronephrotic, 1579, 1580f
 renal parenchymal infiltration by, 1579, 1581f
- Uterine adnexa
 malignant ovarian neoplasms of, 1790, 1791f–1794f, 1792
 ovarian cysts of, 1778–1779, 1780f
- Uterosacral ligaments, 1718
- Uterus, 1718, 1718f
 adenomyosis of, 1777–1778, 1779f
 agenesis of, 2079–2080, 2080f
 bicornuate, 2081, 2081f
 cervical carcinoma of, 1784–1785, 1786f, 1786t, 1787, 1787f
 colorectal carcinoma invasion of, 1482f
 congenital anomalies of, 1776–1777, 1777f, 2079–2081
 embryology of, 2079
 gravid, 1784, 1784f
 hypoplasia of, 2079–2080, 2080f
 in endometrial carcinoma, 1788, 1788f
 leiomyoma of, 1730–1731, 1731f, 1777, 1778f, 1779f
 leiomyosarcoma of, 1732, 1790
 magnetic resonance imaging of, 1760, 1761f, 1762
 pediatric, 2076–2077, 2078f
 neoplasms of, 2088
 sarcoma of, 1789–1790, 1790f
 septate, 1777, 1777f, 2081, 2082f
 tumors of, 1730–1732
 benign, 1730–1731, 1731f
 unicornuate, 2080, 2080f
- Uterus didelphys, 2080–2081, 2081f
- Vacuum cleaner sign, in rounded atelectasis, 854, 854f
- Vagina, 1718, 1718f
 cervical carcinoma invasion of, 1785, 1786f
 congenital anomalies of, 2081–2082, 2082f
 embryology of, 2079
 pediatric, 2076–2077, 2078f
 adenocarcinoma of, 2088
 neoplasms of, 2088
